Before entering upon this, it may be well to consider whether the actual putting forth of the energy of affinity is a phenomenon belonging to physics or chemistry. The answer, open to contradiction by many, is that the study of the energies of affinity is a purely physical question, and not a chemical one. For this reason a chemist deals with those combinations in which the constituent elements have passed through such changes that their identity is lost. The chemist is ever dwelling upon changes, and his equations are not the equations of the physicist and the mathematician; they are, by the use of mathematical symbols, the representatives of change, of what affinity has done and completed, and not of that energy with which it has been done and which is to be measured. The energy of affinity either causes or induces these changes, and until that energy has operated chemistry has no standing ground. The energy of affinity opens the gate which separates the domains of the chemist from those of the physicist, and as the physicist is in possession of the matter the chemist must look there before he can take note of those changes he so loves to contemplate.

It is quite true that when the physicist and mathematician attempt to apply those principles which serve so well in investigating the measurement and utilisations of the other imponderables, they are baffled. By the application and study of these principles it is moderately well known how to call forth that which we wish to call forth. The summons being issued, we can rely upon the same result, whatever may be the surroundings. Not so with the energy of affinity; it is now slow, now sudden, now destructive, now restorative, now brought out by heat, now by light, now by moisture, now by sound, now by time, now by the simple presence of another molecule.

It is similar to the other energies with which we are dealing, in that it seems to consist in a species of attraction or its opposite repulsion. Gravity has a power of attraction at all distances; electricity has both attractive and repellent powers, and we may say at all distances; but affinity is limited to molecules so near that we must say that the matters of which they consist are in absolute and perfect contact.

That there is what we call matter—that it is of such a character or nature as that no two particles of it can at one and the same time occupy the same space; that however much a lump of this matter be divided it may still by finer instruments be sub-divided; that by neither mechanical nor chemical means has any one ever yet obtained one such ultimate and indivisible particle of

matter. These are assumptions generally received without controversy.

It is, however, in and amongst these ultimate and indivisible particles of matter that the laws of affinity operate. If we could handle them as we handle the bulks which the aggregation of these particles form, then, probably, all difficulties respecting the laws of affinity would vanish. We cannot handle them. The physicist gives it up in despair; the chemist, however, more venturesome, deals with them. In dealing with them he puts forth a proposition which the physicist knows not how to accept.

Such unions and interlacings as these seem to set at nought the postulate that no two particles of matter can occupy the same space. For the chemist recognises two, three, four, or five particles of matter, seemingly rushing together, and, as far as we know, occupying the very space which a fundamental physical proposition states they cannot occupy. It may, however, be quite true, for telegraphic messages now-a-days run along the same wire in opposite directions at the same time.

If we could but reconcile these views (and they will be reconciled some day), what a change will come over the dreams of scientific theorists, and what a magnificent and splendid territory for scientific research will then be brought into possession.

To return to the difficulties which interfere with an enunciation of the laws of affinity.

It is plain that explosives, as they are called, vary in their manifestations to our senses in respect of intensity (the assumption that the energy of affinity always produces a species of explosion is not a very violent one). But it is not so plain that within themselves the intensity is a constant quantity, and admits of no variation—that whether gun-cotton causes a cliff to crumble as powder into the sea, or flashes harmlessly without even igniting the gunpowder laid on the palm of the operator's hand, the energy of the affinity in the two cases is exactly the same. In fact, affinity can neither be created nor destroyed—it may be resisted, and if the resistance could be measured at the moment affinity may be said to put forth its energy and overcome the resistance; then this is the measure of the energy. Illustrations of this are numerous and convincing. Let a few minutes be given to one.

If a person raises 100 separate 1 lb. weights off the floor on to a table 3 feet high, then, as a measure of the energy expended, we take the work that is done, viz., 100 separate lbs. raised 3 feet, and call the product 100×3 , viz., 300, as the measure of the energy of vitality which thus raised the weights. Suppose, now, the man had been ten minutes in doing this work, then the energy per minute would be measured by the figures 30. Suppose that instead of working at this rate he had lifted all the weights in one minute, the energy per minute would be still measured by the figures 300, and if the rate of work were continued there would have been expended in ten minutes an energy represented by the figures 3000. Thus we may reason until the work, originally done in ten minutes, is done in one second. The measure of the energy in that one second is 300, and in one minute 18,000, and in ten minutes 180,000. The intensity of the energy in this last experiment is 6000 times as great as in the first experiment. Let this illustration suffice to show that to measure the intensity of an energy time must be taken into account if we wish to utilise that energy, or to bring it into calculations.

It will be within the memory of those present at a former lecture that, in the case of the energy of gravity, Atwood brought time in by staying the sudden action of gravity and distributing the fall of a weight through a large mass. Kater brought time in by causing a pendulum to record the number of its vibrations. They dealt with gravity alone, but as we are dealing not only with the energy of affinity alone, but with such concealed and unknown energies as those which

are taking place, whilst the phenomena we are observing are going on. If we could put two substances together, and could guarantee that neither nascent nor catalytic action should be taking place, then we should have an energy responding as a unit to the energy of gravity. So if we could prolong the time we might, somehow or other, get a record of the energy. But that we cannot do, and with all our modern appliances it seems almost impossible to notice the time when affinity begins and ends its work. Under any circumstances it is difficult to notice time, but when the interval is short, what is called the personal error is as great as though the time were long.

A digression may make this clear. Suppose the eye sees an event, a nerve of sensation conveys the impression to the brain, and then a nerve of motion directs the muscles of the fingers to record it. Now, in the case of affinity, before the nerve of sensation has telegraphed to the brain the commencement of the event whose duration we wish to record, the end of the event is there, and the retina has impression superimposed upon impression, and the fingers fail to enter the records. This leads to another difficulty—the nerves of different persons transmit impressions at different rates; hence observations and records of the duration of things seen and heard by two people do not agree, and certain corrections have to be introduced consequent upon these personal differences in the speed of these nerve-conveying telegrams.

As regards mass. Assuming that our investigations are carried on in the same locality, then, speaking generally, mass is fairly measured by weight *in vacuo*. If the bodies we see and handle were units, then we might recognise mass as the weight of the visible body. These bodies are composed of elemental units, the masses of which we cannot see, and affinity deals with these elemental unit masses, and not with the bodies themselves. Certain considerations, based upon numerous observations, led Dalton and others to conclusions in regard to the weights of these ultimate unit masses. Admitting all to be correct, they are not sufficient for the purpose of estimating the energy of affinity through the fundamental units of time, space, and mass.

The failure is thus—Dalton, finding hydrogen the lightest substance, compared all others with it. But what is the actual weight of a hydrogen atom? That we do not know, therefore we cannot know the weights of the other substances which are recorded in this.

If the absolute weight of one elemental unit of any simple body could be had, then, thanks to Dalton and others, the absolute weight of the unit elements of all other bodies is known.

For the purpose of making clear the value of these atomic or molecular elements in reference to their mass and the space between them, let me, at the risk of some repetition, remind you that knowing the weight of one atom or molecule of each of the bodies, the energy of whose affinities is to be measured, and knowing the space between them and through which space these atoms or molecules pass before they coalesce, then the product of these two elements gives the value of the energy in the form of work done. If with this product the time is combined, then not only the energy, but the intensity of the energy is also known.

Now, if we cannot get at the unit masses, how can we possibly get at the distance between them; yet this distance is the space through which these little masses must be carried by the influence of that affinity whose energy is to be measured by the work it does.

When, however, we consider that the waves of light have been measured, the number of them, per inch, stated, their velocity ascertained, we have good grounds for assuming that the masses and distances of the ultimate elements of matter will also be ascertained; then the laws which regulate the energies of such affinities will, most probably, be also ascertained.

Such are some of the preliminary difficulties which

present themselves to those who look in hope to establish the laws which govern the energies of affinity from first principles.

If, however, these laws be enunciated—if they be even approximately attained—it will most probably be through some indirect means, through some other energies from which these energies of affinity may be deduced. In this indirect way the mechanical energy of heat has been measured, and its value is as generally received and acted upon as that twelve pence make one shilling or twenty shillings make one pound.

The source of mechanical power, so far as men utilise it, is in the energies of affinities. To these energies, as formed by the Creator (inherent and primordial), we owe the means by which work is done. Indeed, it is no very bold suggestion to make, that to the exercise, even now, of these inherent affinities, we owe much—it may be all—of terrestrial magnetism and internal terrestrial change and heat; the progress, in the depths of the earth, of these affinities, may be the cause of the variation of the compass; nay, we cannot tell where speculations such as these lead. How the atoms disport themselves we know not; this we do know, that when some atoms meet some other atoms they are as Greek joined to Greek, for "then comes the tug of war."

(To be continued.)

CORRESPONDENCE.

TURACIN.

To the Editor of the Chemical News.

SIR,—On my return lately from Angola, I had an opportunity of purchasing, from the natives in the Market at Sierra Leone, a quantity of the beautiful red feathers of the "plantain-eaters;" and, being desirous of verifying the extraordinary results published by Mr. Church in the *Phil. Trans.* for 1869, I gave them to my friend, Mr. Henry Bassett, F.C.S., to examine, and he has kindly supplied me with the following note as the result of his investigation:—

"From 300 feathers obtained 1045 grms. turacin. Two copper determinations, made by fusing with nitre and carbonate soda, washing out with water, then dissolving the oxide of copper in nitric acid, filtering, and precipitating with potash, gave quantities of oxide copper corresponding to 7.6 and 8.0 per cent of metallic copper. Church found 6.0 per cent; on the other hand, the feathers yielded him a larger quantity of the colouring matter. General characters, appearance, &c., exactly in accordance with Church's description; insoluble in benzol, sulphide carbon, tetrachloride carbon. The copper to be unmistakably seen by burning the smallest portion of a feather in a Bunsen burner."

These lovely birds are common on the west coast of Africa, and on that part of it that I am well acquainted with, viz., from Loango, in 5° S. lat., to Little Fish Bay, in 15° S. lat., their loud and prolonged cry is to be frequently heard in the thick forest, where they find their fruit food most plentifully. Over the whole of the country I have mentioned, and for a considerable distance inland, copper is found most abundantly distributed as malachite, or green carbonate; in fact, specks and indications of the green mineral are to be noticed almost everywhere. Whether such is also the case on the west coast, at Sierra Leone, Senegal, &c., where these birds are, I believe, still more usually found, I cannot say; but there is no doubt that in the large extent of country I have mentioned and explored for many years, and where these birds are common, copper is found very extensively disseminated. I am unable to say whether the copper enters their system as a constituent of their food, as suggested by Mr. Church, but I believe it most probable that these birds are attracted by the bright green of the malachite,

and swallow small particles of it with the gravel, &c., that they, in common with all birds, consume with their food.

These red wing-feathers are sold and used by the natives of the west coast as a "fetish," being employed as charms in sickness, &c., and the bird itself in Angola is considered as a great "feiticeiro," or witch, being said to warn travellers with its loud cry from danger of robbers, animals, &c., lying in wait to attack them; and its cry, if uttered in a village or town, is reckoned as a very bad omen.

Trusting the above notes, in verification and explanation of Mr. Church's singular results, may prove interesting to your readers, I am, &c.,

J. J. MONTEIRO,
Associate of the Royal School of Mines.

AN INDIGNANT PROTEST.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS of August 8, 1873, an article is published which gives an account of the alleged "discovery," by a French chemist, of a "new" method of estimating iron by means of the decolorisation of the blood-red solution formed by adding sulphocyanide of potassium to one containing iron peroxide.

If you refer to your file of the CHEMICAL NEWS for 1868, you will find published there (I forget in which month) a letter from me suggesting this very operation; and my suggestion was negatived in the next number of the CHEMICAL NEWS by (I think) a Mr. Wright, who satisfactorily (to the English chemists) proved that it was "impossible." I quite agree with the Frenchman that nothing is "impossible," but he might have had the justice, and you the memory, to give me credit for the "idea."—I am, &c.,

W. A. ROSS.

Shooter's Hill, Kent,
Oct. 8, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 15, 1873.

Products of Oxidation of Meteoric Irons compared with the Terrestrial Magnetites.—According to considerations already developed the terrestrial rocks, taken in their totality, behave like the epidermis of a globe whose lower regions are constituted by masses resembling the meteoritic rocks. Veins of ferrous oxide may be taken to represent the upper portions of veins of massive iron comparable to the siderites. On oxidation under certain conditions the nickel is eliminated. The characteristic structure of meteorites is found to be entirely destroyed by oxidation. A fragment of iron from Charcas was heated to redness for five hours in a current of steam. It was then allowed to cool, the coherent mass of oxide was polished, and then treated with very weak hydrochloric acid according to Widmanstätten's procedure, but no figure appeared.

Preparation of a New Anilin Red.—M. E. Ferrière.—An acetate of anilin is formed, mixed with ammoniacal

hydrate of copper, and saturated with sulphuric acid, when a fine purple-red colour is developed. After concentration the liquid on standing deposits crystals of sulphate of ammonia, which are filtered off. The new anilin-red remains then transparent.

Reply to M. Tacchini's Last Note.—M. Faye.—M. Tacchini had cited (as in opposition to M. Faye's theory) the case of two spots observed by the Italian spectroscopists, in which the internal gyration was in contrary directions, although the spots were in the same hemisphere. The author reproduces drawings of these spots, and points out that one of them is in advanced segmentation; and that one segment is gyrating in one direction, the other in the opposite. Now, only intact spots (as he had before said) should be compared. Then M. Tacchini again insists on the appearance of protuberances where there are not spots. M. Faye, with the view of elucidating this point, makes the following propositions:—(1) The sun's surface is studded with innumerable pores, giving a shagreened appearance. Those with appreciable dimensions have a diameter of at least one second, representing an opening of 167,000 square miles. (2) The spots are enlarged pores. (3) The spots finish as they commence, returning to the state of pores, finally imperceptible. (4) In these successive transformations there is one element which is unchanged, viz., the primitive axis of the pore. (5) There are two zones parallel to the equator where the change of pores into spots is frequent, and where the spots retain enormous size a long time before becoming pores again. (6) Beyond these zones, at the two polar calottes and the equator, the pores only become spots for a few instants. The phenomenon is very rare from 40° lat. north or south in each hemisphere, and beyond 52° the pores never acquire the size of spots. All this being allowed, M. Faye's theory attributes the circulation of hydrogen to the mechanical action of pores, these being considered as vertical cyclones produced by the unequal velocity of contiguous zones of the photosphere. When the pores are accumulated in certain regions they may give exceptional activity to this circulation and produce protuberances. The heliographic distribution of these, therefore, simply indicates pores more or less accumulated. In times of exceptional cyclonic activity groups of pores, and consequently protuberances, should appear near the poles and near the equator, and this agrees with fact. The pores become spots where the cyclones have most stability. These spots produce more marked protuberances than accumulation of pores does elsewhere; but it is by the same mechanical action. In short, the solar vortices, both spots and pores, produce protuberances; hence it is not surprising that protuberances appear where there are no spots. The author adds sketches of the development of a pore into a spot, and the return to the original state.

New Researches on the Analysis and Theory of the Pulse in the Normal and the Abnormal States.—M. Bouilland. (Extra.)—The author distinguishes four periods in each "arterial revolution," or the changes occurring from commencement of one pulsation to that of the next. Of the two shocks the first (known as the pulse) is produced by the ventricular systole of the heart; the second results from systole of the arteries (which are passive in the first, active in the second). These two alternating shocks constitute the normal *dicrotism*, of which the abnormal *dicrotism* is merely the intensifying, simple or double, that is affecting either one shock or both. In opposition to Harvey and other physiologists, the author supposes in the arteries an *impulsive* force without which the transport of the blood into all parts of the body could not be effected. The co-ordinated movements of arteries and heart are ruled by ganglionic innervation, but the precise situation of the co-ordinating nerve-centre has yet to be discovered.

Changes of Form of the Comet 1873, IV.—MM. Rayet and André.—This comet (of which a drawing is given), as observed on the night of September 3, had 2

tail about 2° long, while the head was about eight or nine minutes diameter. The nucleus, at first in the centre of the nebulosity, had taken an excentric position near the part furthest from the tail. Other details are given.

Motion of an Elastic Wire, one Extremity of which is Animated with a Vibratory Motion.—M. Mercadier. —The author has studied, with the aid of his "electro-diapason" (formerly described), the motion of an elastic wire fixed to one of the extremities perpendicularly to the plane of vibration. Taking any length of wire, one or other of two cases will occur. (1) The wire divides into a certain number of concamerations with a free extremity, the vibration of which, like that of the whole wire, is executed parallel to that of all the points of the diapason. A node seems at greater or less distance from the diapason, the vibratory intensity and amplitude of which are not sensibly altered by the presence of the wire. This case is distinguished as the *normal vibratory state*. (2) The wire presents complex vibratory forms indicating superposition of movements, and sometimes "turning" vibrations. The free end from the last node takes the form of a horn of varying section. This case especially occurs where the wire is thin; and in all such vibratory states (termed *abnormal or transitional*) there is a diminution of the amplitude and intensity of movement of the diapason, which may even extend to extinction. In the present note the normal vibratory state is studied. The number of nodes, the nodal distance, and the length *l* vibrating freely, depend on the length *L* of the wire, its diameter, and the number of vibrations of the diapason. From a table of results several laws are deduced. [*D* stands for the first nodal distance, or distance from the first node to the second; *D* the other nodal distances, except the last, called *d*; after the last node comes *l*.] (1) Whatever the length, where the wire vibrates regularly, it always vibrates synchronously with the diapason. (2) For the same wire the nodal distances, except the first *D* and the last *d*, are equal. (3) For the same wire, whatever the length, *l* is constant and equal to the third of the normal nodal distance *D*. (4) The length of the wire being varied, *l*, *d*, and *D* remain invariable till there is only one node; the distance of the first node from the diapason alone varies. (5) Other things equal, the normal nodal distance of wires of the same nature are to each other as the square roots of their diameters. (6) For different diapasons, the normal distances corresponding to the same wire are inversely as the square roots of the number of vibrations of the diapasons. (7) If the amplitude of the diapason is varied (e.g., by varying gradually the intensity of the pile) the form of vibration of the wire does not change, but the three or four first nodes near the diapason are displaced; removing from, or approaching it, according as its amplitude is increased or diminished. This displacement decreases very rapidly from the first to the last node displaced.

Product of Oxidation of Meteoric Irons; Comparison with Terrestrial Magnetites.—M. S. Meunier.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, September 3, 1873.

On Silver Urea.—E. Mulder.—The author formed a compound of urea and silver by precipitating with soda a mixed solution of nitrate of silver and urea. It is a gelatinous light yellow precipitate. Silver urea is insoluble in water, but soluble in ammonia. It consists of—

Carbon	4.4
Hydrogen	0.8
Nitrogen	9.8
Silver	78.8

and its formula is probably CO_2NHAg . It does not explode when heated like silver carbodiimid.

Behaviour of Monochlor-Phenol Boiling at 218° on Fusion with Potassa.—Ang. Faust.—The author finds himself unable to confirm the results of Petersen and

Bæhr Predari, who allege that they obtained hydrochinon on fusing monochlor-phenol with hydrate of potassa.

On Oxethenanilin.—E. Demole.—By allowing ethylen-oxide to act upon an equivalent quantity of anilin in a sealed tube the author obtained a new base, $\text{C}_8\text{H}_{11}\text{NO}$. It consists of—

Carbon	70.08
Hydrogen	8.31
Nitrogen	10.64

This base is less mobile than anilin, colourless when recently prepared, sparingly soluble in water, alcohol, and ether, but readily in chloroform. The aqueous solution takes a green colour with solution of hypochlorite of lime.

Examination of Human Bile.—Oscar Jacobsen.—The bile appeared as a clear greenish brown-yellow, and perfectly neutral liquid. The specific gravity at 17.5° C. ranged from 1.0105 to 1.0107, and the percentage of solid matter was from 2.24 to 2.28. Only in the first days traces of albumenoid bodies and of leucin were found in the bile. Grape-sugar and urea were not present. Of the better known bile pigments bilirubin and biliverdin were found. The mineral ingredients were:—

	Percentage of the Ash.	Percentage of Dried Bile.
KCl	3.39	1.276
NaCl	65.16	24.508
CO_3Na_2	11.11	4.180
PO_4Na_3	15.90	5.984
$(\text{PO}_4)_2\text{Ca}_3$	4.44	1.672
	100.00	37.620

Very small quantities were found of iron, silicic acid, and magnesia. Traces of copper were sought for on three occasions, and were found on each. The copper was only in the portion of the bile insoluble in alcohol. **Organic Constituents**—3.14 per cent of the dried residue dissolved in ether—

Cholesterolin	2.49
Unsaponified fats, with a little oleate of soda	0.44
Leeithen	0.21
	3.14

The organic substances insoluble in ether and alcohol formed—Of the solid residue, 10.0. The alcoholic extract—Glycolate of soda, 44.8; palmitate and stearate of soda, 6.4. On the prolonged boiling of human bile with hydrate of baryta trimethylamin was invariably obtained, whence cholin may be regarded as a normal constituent of human bile.

Silico-Acetic Acid and its Ether.—A. Ladenburg.—The ether has the formula $\text{SiCH}_3(\text{OC}_2\text{H}_5)_3$. Its specific gravity at 0° = 0.9283. It is soluble in alcohol, insoluble in water, but is gradually decomposed thereby. The density of its vapour in toluidin vapour amounts to 170.8, H being calculated = 2; and its molecular weight = 178. In other respects it is similar to ortho-silico-propionic ether.

Oxymethan-Sulphonic Acid, and Oxymethan-Disulphonic Acid.—Max Müller.—The author has obtained the two acids, and gives the structural formulæ.

Composition of Cascarillin.—C. Mylius and E. Mylius.—Cascarillin and ricinin are decidedly unlike. Ricinin is a well marked base, whilst cascarillin is indifferent to alkalies and acids, and contains no nitrogen. Its formula is $\text{C}_6\text{H}_4\text{O}_2$, and its composition—

Carbon	63.71
Hydrogen	7.97
Oxygen	28.32
	100.00

Product of the Oxidation of Caryophyllin.—E. Mylius.—The author obtained and examined caryophyllinic acid, $\text{C}_{20}\text{H}_{32}\text{O}_6$, composed of—

Carbon	65.22
Hydrogen	8.69
Oxygen	26.09

100.00

The salts of soda, silver, and baryta were likewise prepared and analysed.

On Nitro- and Amido-Benzylamid.—Julius Strakosch.—The author has prepared and analysed the hydrochlorate of secondary nitro-benzylamin, the free base itself, $C_{14}H_{13}N_3O_4$; tertiary nitro-benzylamin, $C_{21}H_{18}N_4O_6$; secondary amido-benzylamin, the hydrochlorate of which is $C_{14}H_{20}N_2Cl_3$; tertiary amido-benzylamin, $C_{21}H_{24}N_4$; hydrochlorate of nitro-benzyl-phenylamin, $C_{13}H_{13}N_2O_2Cl$; and hydrochlorate of amido-benzyl-phenylamin, $C_{13}H_{16}N_2Cl_2$.

On a Polymeric Modification of Isobutyl Aldehyd.—G. A. Barbaglia.—The author acted upon isobutyl aldehyd with bromine and iodine, and obtained polymerised modifications melting at 60° C., very permanent, reducing salts of silver slowly without forming a silver mirror. The variety polymerised by bromine gave—

Carbon	66.666
Hydrogen	11.111
Oxygen	22.223

100.000

It is probably a tri-molecular modification of isobutyl-aldehyd.

Action of Pyromellithic Acid upon α -Naphthol.—Julijan Grabowski.—The following is a conspectus of the substances formed and examined:—

- No. 1. Di- α -naphthol-pyro-mellithic acid —
 $C_{10}H_6O_8 + 2C_{10}H_8O - 2H_2O = C_{30}H_{18}O_8$.
- No. 2. Tri- α -naphthol-pyro-mellithic acid —
 $C_{10}H_6O_8 + 3C_{10}H_8O - 3H_2O = C_{40}H_{24}O_8$.
- No. 3. Tri- α -naphthol-hemianhydrid-pyro-mellithic acid —
 $C_{10}H_6O_8 + 3C_{10}H_8O - 4H_2O = C_{40}H_{22}O_7$.
- No. 4. α -, β -, and γ -tetra- α -naphthol-hemiar hydrid-pyro-mellithic acid —
 $C_{10}H_6O_8 + 4C_{10}H_8O - 5H_2O = C_{50}H_{28}O_7$.
- No. 5. Pyro-mellithic-tetra- α -naphthol-anhydrid —
 $C_{10}H_6O_8 + 4C_{10}H_8O - 6H_2O = C_{50}H_{26}O_6$.
- No. 6. Phthaleindi- α -naphthol —
 $C_8H_6O_4 + 2C_{10}H_8O - 2H_2O = C_{28}H_{18}O_4$.
- No. 7. Phthaleindi- α -naphthol-anhydrid —
 $C_8H_6O_4 + 2C_{10}H_8O - 3H_2O = C_{28}H_{16}O_3$.
- No. 8. Carboneindi- α -naphthol-anhydrid —
 $CO(OH)_2 + 2C_{10}H_8O - 3H_2O = C_{21}H_{12}O_3$.

Combinations of Chloral with Sulphuric Acid.—Julijan Grabowski.—A compound of this nature is obtained by the action of anhydrous sulphuric acid upon chloral. It has the formula $C_{10}H_9Cl_3S_3O_{16}$. It is the most permanent of all the sulphuric compounds of chloral. If cautiously heated with alcohol it dissolves and crystallises out unchanged on cooling.

Reply to Couper's Reclamation on the Preparation of Magenta without Arsenic Acid.—A. Brünig.—The author declares that his procedure, though founded on the same reaction, is essentially different from that of Couper, producing magenta at a far lower price, and of much superior quality.

Laws Governing the Molecular Rotatory Power of Tartaric Acid and its Salts.—H. Landolt.—This paper is not adapted for abstraction.

Nature of the Elements.—G. A. Groshans.—A mathematical paper, likewise not suited for abstraction. The author concludes with the remark that if the specific volumes of two bodies which differ from each other by an atom CH_2 , or an atom of any other element or other atomic group from their respective boiling-points, remainders are occasionally obtained which may be considered as approximately equal.

Benzylised and Dibenzylised Acetic Acid.—Lydia Sesemann.—The authoress, an alumna of the University of Zurich, has obtained benzyl-acetic acid, $C_9H_{10}O_2$, and dibenzyl-acetic acid, $C_{16}H_{16}O_2$, and is at present engaged with studying the most important derivatives and metamorphoses of the latter.

Examination of Certain Bodies of the Camphor Group, Carvol and Carvacrol.—Aug. Kekulé and A. Fleischer.—Carvol is obtained by fractional distillation of the oil of caraway, and boils at 224.5° . It was converted into carvacrol by the action of ortho-phosphoric acid. It boils at 232° to 232.5° , and is isomeric with thymol. Neither carvol nor carvacrol yields any well-characterised product with oxidising agents, except oxalic acid. Perchloride of phosphorus acts upon carvacrol in the same manner as upon the more simple phenols. The sulphacid of carvacrol is solid and crystalline, and its salts can be obtained in fine crystals.

On Bromo-Campho-Carbonic Acid.—J. de Santos e Silva.—The action of bromine upon campho-carbonic acid is very energetic, hydrobromic acid being evolved. If the mixture heats decomposition takes place, but if the temperature is kept down a crystalline yellowish product is obtained, perfectly soluble in dilute soda or potassa-lye. From this solution hydrochloric acid throws down monobromo-campho-carbonic acid as a white powder, —
 $C_{11}H_{15}BrO_3$.

On Terebic and Pyroterebic Acids.—W. Carleton Williams.—Pure terebic acid melts at 175° , whilst Caillot gives 168° . The statement of Svanberg that terebic acid yields both terebates, $C_7H_9MO_4$, and diaterbates, $C_7H_{10}M_2O_3$, was confirmed. Pyroterebic acid was obtained by the dry distillation of terebic acid; it boils at 210° . With bromine it combines to form dibromocapronic acid.

On Ethyl-Crotonic Acid.—W. Petrieff.—Ethylcrotonic acid is isomeric with pyroterebic acid. On fusion with potassa it is split up into acetic acid and butyric acid, the latter probably the isobutyric.

Derivatives of Normal Propylic Alcohol.—H. Roemer.—The author, acting on propylic alcohol with phosphene gas, obtained chloro-carbono-propylic ether, and a liquid heavier than water, burning with a green flame, and giving off a pungent odour. Its formula is $C_4H_7ClO_2$.

Action of Bisulphide of Carbon upon Paranitranilin.—A. Brückner.—A preliminary communication. **Certain Homologues of Oxaluric Acid.**—W. H. Pike.—This has already appeared in our columns.

New Synthesis of Propionic Acid.—J. H. van Hoff.—The acid was found amongst the products obtained by exposing to heat oxalate of potassa and dry sodium ethylate.

Contributions to the History of the Polythionic Acids.—W. Spring.—The author has studied the action of chloride of sulphur upon the sulphites. Among the results were trithionate of potassa, and hyposulphite of potassa.

Certain Derivatives of Benzophenon.—Julius Beckmann.—On treating benzophenon with fuming sulphuric acid the author obtained a body, $C_{12}H_8SO_3$. Its lead and baryta salt were formed and analysed, and it was submitted to the action of pentachloride of phosphorus, yielding a new body not yet fully examined.

Cyan Derivatives of Acetaldehyd and Aldehyd-Ammonia.—F. Urech.—By mixing equivalents of acetone, CNK and CNOK, with acids acetonyl-urea was obtained. To prepare lactyl-urea instead of the aldehyd, which easily becomes resinous in a basic liquid, its ammonia compound was used. In this manner lactyl-urea was prepared, which the author had previously obtained from CNOH and alanin.

On Nitronaphthol.—R. Biedermann.—The author has examined the compounds of nitronaphthol with

potassium, sodium, ammonium, barium, calcium, lead, and silver. A bromated substitution product, dibrom-naphthol, $C_{10}H_5Br_2OH$, was also obtained and analysed.

A Reply to Barbaglia.—G. Kræmer.—A controversial paper on isobutylic aldehyd and isobutylic alcohol.

New Resin Acid—the Podocarpinic.—A. C. Oudemans, jun.—The composition of the acid may be expressed as $C_{17}H_{22}O_3$. It fuses at 187° to 188° , and is not decomposed below 330° . Several of its salts and its nitro and sulpho derivatives have been examined. The acid was obtained from a kind of resin extracted from a Javanese tree, *Podocarpus cupressina*.

Constitution of Podocarpinic Acid.—A. C. Oudemans, jun.—A continuation of the foregoing paper.

Base from Nitrobenzanilid.—H. Hübner and H. Retschy.—The authors have examined the salts of the base $C_{13}H_{10}N_2$.

Javanese Cinchona Barks.—Jul. Jobst.—A paper chiefly of pharmaceutical and botanical interest.

Annalen der Chemie und Pharmacie, band clxviii., heft 2 and 3 (Neue Reihe, band xcii., heft 2 and 3), August 30, 1873.

Preparation of the Sulpho-Acids.—W. Hemilian.—The author modifies Strecker's method by operating upon the haloid derivatives of organic compounds with the sulphite of ammonia instead of the sulphite of potassa.

On certain Haloid Derivatives of Toluol.—Dr. E. Wroblewsky.—The author describes first the bromated, and then the chlorated, compounds of toluol. He has formed and examined—Aceto-meta-brom-para-toluidin—

Meta-brom-para-toluidin, $C_6H_3Br(CH_3)NH_2$; with its nitrate, $C_7H_6BrNH_2NHO_3$; its hydrochlorate—

its acid oxalate, $C_7H_6BrNH_2C_2H_2O_4$; its acid sulphate, $C_7H_6BrNH_2H_2SO_4 + H_2O$. Meta-brom-toluol—

with its lime salt, $(C_7H_4BrO_2)_2Ca + 3H_2O$; and its baryta salt, $(C_7H_4BrO_2)_2Ba + 4H_2O$. He has further obtained—The hydrochlorate of brom-toluidin; the nitrate; the baryta salt, $(C_7H_4BrO_2)_2Ba + 4H_2O$. The author next describes the reactions of—Diazo-meta-brom-toluol;

meta-brom-para-iodo-toluol, $C_6H_3I_pBr_mCH_3$; the nitro-para-iod-meta-brom-toluol, $C_6H_2NO_2I_pBr_mCH_3$. He examines the preparation of meta-brom-toluol on the decomposition of diazo-meta-brom-per-bromide, and the preparation of meta-brom-toluol from ortho-toluidin; aceto-meta-brom-ortho-toluidin—

Meta-brom-ortho-toluidin, $C_6H_3Br_m(CH_3)NH_2$; its hydrochlorate, $C_7H_6BrNH_2HCl$; nitrate—

and sulphate, $(C_7H_6BrNH_2)_2H_2SO_4$. Meta-brom-ortho-iod-toluol, $C_7H_5BrI_o$; nitro-meta-brom-ortho-iod-toluol, $C_7H_5NO_2BrI_o$; meta-brom-ortho-cresol—

The sulpho derivatives of meta-brom-toluol; with the α barytic salt, $(C_7H_6Br_mSO_3)_2Ba + H_2O$; the potash salt; the β barytic salt, $2[(C_7H_6Br_mSO_3)_2Ba] + 3H_2O$; the β lead salt, $(C_7H_6Br_mSO_3)_2Pb + 3H_2O$; the β lime salt, $2[(C_7H_6Br_mSO_3)_2Ca] + 5H_2O$; the β potassic salt, $C_7H_6Br_mSO_3K$. The ortho-sulpho-meta-brom-toluolic acids have the constitution $1:2:3$ and $1:3:6$, and both, therefore, yield salicylic acids. The γ barytic salt—

nitro- β -meta-brom-ortho-sulpho-toluolate of baryta—

and the lead salt $[C_7H_5Br_m(NO_2)SO_3]_2Pb + 3H_2O$; and the corresponding lime salt—

Meta-brom-toluol was found to yield two nitro-derivatives— α , solid, and β , liquid. The author next examines—Ortho-brom-toluol and its derivatives, particularly ortho-brom-

toluol and the results of its oxidation; dibrom-toluol; the preparation of ortho-brom-toluol from meta-toluidin; ortho-brom-meta-toluidin, with its nitrate. He next investigates para-brom-toluol and its derivatives— α solid para-brom-ortho-nitro-toluol; β liquid para-brom-meta-nitro-toluol; α -para-brom-ortho-toluidin; β -para-brom-meta-nitro-toluidin, with the α and β nitrates. The author remarks that the theory of the aromatic compounds indicates the existence of six isomeric dibrom-toluols. He next proceeds to the tribrom-toluols, and to the chloric substitution-products of the isomeric toluidins and of their derivatives.

On Selenic Acid and the Seleniates.—Dr. v. Gerichten.—In this paper the author gives a simple and certain method for the preparation of hydrous selenic acid. His attempt to produce the anhydrous acid yielded a mixture of the substance sought and of selenious acid. He finds it possible to prepare alums in which selenic acid replaces either the sulphuric acid in combination with potassa, or that united to alumina. The same result may be attained with the double salts of the formula—

It is possible in all these salts to replace the sulphuric acid, molecule for molecule, by selenic acid, and the prodigious mass of salts thus obtained are all isomorphous with the two extreme members of the series—the pure sulphuric and the pure selenic double salts.

Action of Trisulpho-Carbonate and Sulpho-Carbonate of Ammonia upon Aldehyds and Aceton.—E. Mulder.—Acetonin was obtained by the action of ammonia upon aceton, and subsequent addition of aqueous oxalic acid, and its trisulpho-carbonate was then formed and examined.

New Formation of Ortho-Toluilic Acid.—R. Fittig and W. Ramsay.—This paper is not suitable for abstraction.

On Meta-Toluilic Acid.—C. Boettinger and W. Ramsay.—The authors find that what Ahrens and Tawildarrow took to be pure meta-toluilic acid was a mixture of this salt with more or less para-toluilic acid.

MISCELLANEOUS.

Prize List of the Société Industrielle de Mulhouse.

—The following is a translation of the list of prizes offered by this Society; with very few exceptions, they are open to general competition. They will be decided in May, 1874. There are three classes of medals, all of bronze, but differing in size:—Medals of honour; 1st class medals; and 2nd class medals.

GENERAL PRIZES.

CHEMICAL ARTS.

1. An essay on the theory of the manufacture of Turkey red. (1st class medal.)
2. A theoretical essay establishing the chemical constituents of the substance, or substances, which accompany alizarin in garancin, and which, in concert with this colouring matter, produce the dyes called garancin. (1st class medal.)
3. For the manufacture and delivery to the calico manufactories of Alsace of an artificial product, capable of entirely replacing the colouring matter of garancin, and which, both as regards price and quantity is fitted for industrial purposes. (Medal of honour.)
4. For the preparation of vivid lakes from garancin, both red and violet. (Medal of honour.)
5. For a substance which can be used to thicken colours, sizes, or dressings, and which will replace, at a saving of at least 25 per cent, all the substances hitherto employed for these purposes. (Medal of honour.)
6. For a substance which can replace the dry albumen of eggs in the manufacture of printed calicos, and give a large saving on the price of albumen. (Medal of honour.)
7. For colourless albumen from blood, which will not colour by evaporation. (Medal of honour.)
8. For an important improvement in the bleaching of wool or silk. (Medal of honour.)
9. For a method of bleaching which will remove from unbleached cotton all amylaceous substances, without injuring the tissue, and without any great increase of expense. (Medal of honour.)
10. Essay on the employment of resins in the bleaching of cotton fabrics. (1st class medal.)

11. For an ink for marking cotton fabrics intended to be dyed with plain grounds, red, puce, and other dark colours. This ink must show plainly after undergoing all the operations required for these dyes. (1st class medal.)
12. For an essay on the action of different kinds of cotton under processes for bleaching and colouring. (Medal of honour.)
13. For a blue which can be used for dyeing wools blue, and which will resist the action of steaming and light. (1st class medal.)
14. For any improvement in chemical products as regards purity and concentration—acids, alkalies, soaps, colouring matters, and decoctions. (1st class medal.)
15. For one or other of the following colours:—Metallic red, dark metallic green, metallic violet, garnet, and a shade of the series from pearl grey to dark, capable of being printed by rollers with albumen as thickening. (Medal of honour.)
16. For a theoretical and practical essay on cochineal red. (Medal of honour.)
17. For a transparent green, resisting light and soap, whose brightness, intensity, applicability to cotton fabrics, and price, render its use possible in manufactures. (Medal of honour.)
18. For an essay on this question: Can indigotin be recovered from its sulphuric acid compounds? (2nd class medal.)
19. For the first who delivers to the calico manufactures of Alsace an artificial product replacing advantageously the blue colouring-matter of indigo. (Medal of honour.)
20. For the first who delivers to the calico manufactures of Alsace an artificial product replacing advantageously the sulphuric acid derivatives of indigo. (1st class medal.)
21. For a new process of fixing, by printing, anilin colours in a more complete way than by albumen. (1st class medal.)
22. For an anilin black, soluble in any vehicle, which can serve as a dye, and can resist the action of light and soap, as well as true anilin black. (Medal of honour.)
23. For a new black of the same intensity and the same solidity as anilin black, which will not weaken the fabric, and will bear contact with all other colours, especially those mixed with albumen, without itself injuring the shades with which it is associated. (1st class medal.)
24. For an essay on the composition of anilin black. (Medal of honour.)
25. For a scarlet red susceptible of applications similar to those of the anilin colours, which will not be more fugitive than them, and not dearer than a cochineal crimson. (Medal of honour.)
26. For any reproduction, by an artificial or natural alkaloid, of the reactions which, with aniline, toluidine, naphthylamine, produce red, blue, green, and black. The essay should be accompanied with samples, and will receive a prize even if industrially inapplicable. (Medal of honour.)
27. For a method of increasing the solidity of artificial colouring matters. (Medal of honour.)
28. For a certain and practical method of bringing anilin black, immediately after printing, to the maximum of oxidation, without having recourse to ageing, and without damaging the fabric or injuring the metal employed for printing. (1st class medal.)
29. For the introduction into manufactures of calicos printed in a new colour, which is developed and fixed under conditions analogous to those under which anilin black is produced; which shall also be impervious to air and light, and resist the action of soap, alkalies, and acids. (Medal of honour.)
30. For a metallic alloy or other substance fitted to serve for doctors, and which unites to the elasticity and hardness of steel the property of not causing any chemical action in the presence of acid colours, or colours charged with certain metallic salts. (Medal of honour.)
31. For any great improvement in the engraving of cylinders. (Medal of honour or 1st class medal.)
32. For the best practical manuals on one or other of the following subjects:—(1). Engraving/printing cylinders. (2). Engraving/printing blocks. (3). Bleaching cotton, wool, and cotton, silk, hemp, and linen. (Medal of honour of the 1st or 2nd class, according to the merit of the essay.)
33. For an essay on this question: At what degrees of damp and heat does the decomposition of mordants act with most rapidity and most advantage? (1st class medal.)
34. For a new cylinder machine, able to print at least eight colours at a time, and offering some advantages over those at present employed. (Medal of honour.)
35. For introducing or manufacturing in Alsace cylinders of cast-iron, covered with copper by electro-plating, which are to be used in printing calicos. (Medal of honour.)
36. For a series of new colours, with metallic bases, unchangeable by the action of air and light. These colours, specially intended for use as plain colours, must be fixed otherwise than by albumen, and be able to bear washing. (Medal of honour.)
37. The best system of vats for dyeing and soaping. (1st class medal.)
38. For the discovery or introduction of a method useful in the manufacture of printed fabrics or chemical products. (Medal of honour of the 1st or 2nd class.)
39. For a method of recovering the sulphur contained in hydrosulphuric acid. (1st class medal.)
40. For an apparatus transmitting thermometrical indications to a distance. (1st class medal.)
41. For an apparatus marking automatically the temperature and the hygrometrical state of the air in the drying-houses of calico factories. (1st class medal.)
42. For a new method of treating the different kinds of oil used for lubricating machines. (Medal of honour.)
43. For an essay on the relative inflammability of the animal, vegetable, and mineral oils used in workshops for lubricating machines. (1st class medal.)

44. For an essay indicating some process by which mineral oils may be rendered less inflammable while their lubricating properties are preserved. (Medal of honour.)
45. For the production of carminic acid by synthesis. (Medal of honour.)
46. For introducing into manufactures artificial orcin. (Medal of honour.)
47. For the preparation of vermilion on cotton fabrics. (Medal of honour.)
48. For a blue, analogous to ultramarine as to shade and solidity, to be fixed on fabrics of cotton by a chemical process, without the help of albumen or any other thickening substance producing adhesion by coagulation. (Medal of honour.)
49. For a practical method of extracting from garancin the orange-red colouring matter, the price of which will admit of the use of this product in printing cotton fabrics. (Medal of honour.)
50. For the first delivery to the cotton factories of Alsace of a pipe-clay, either natural or artificial, in impalpable powder, which will serve to thicken the colours used for cylinder printing; it must be entirely free from the hard and sandy substances which nearly always accompany it. (2nd class medal.)
51. For the best system of vats for dyeing. (1st class medal.)
52. For the production of carminic acid by synthesis.

MISCELLANEOUS PRIZES.

31. For a new method of treating the different kinds of oil proper for lubricating machines. (Medal of honour.) (See prize No. 42 for Chemical Arts.)
37. For a new machine for cylinder printing, capable of printing at least eight colours at a time, and offering advantages superior to those now in use. (Medal of honour.) (See No. 34 of the Chemical Arts' prizes.)
38. For an alloy of metal, or other substance, fitted to replace advantageously, under all circumstances, the gun-metal employed in the construction of machines. (1st class medal.)
42. For the invention and application of a pyrometer capable of gauging the temperature of the gaseous products of the coal burned under steam generators. (Medal of honour.)
52. For a new burner for coal-gas, utilising more thoroughly than known burners the light produced by combustion; it must be simple and cheap, and grounded on a new principle. (Medal of honour.)
53. For a simple automatic method of regulating the admission of steam into bleaching or dyeing vats, so that the consumption of steam may always correspond with the desired result. (Medal of honour.)

PRIZES OF THE COMMITTEE OF COMMERCE.

1. For an essay treating of the different uses of alcohol in the industrial arts and pointing out a new and practical way of "denaturalising" this liquid. The process indicated must reconcile the interests of industries with the demands of the excise. (Medal of honour.)
6. For researches made in China or Japan with the object of procuring from these countries raw material which will save at least 20 per cent in producing certain chemical products, such as tartaric acid, citric acid, borax or boric acid, &c. (1st class medal.)
11. For the person or society which introduces and practises the culture of madder in Algeria. (1st class medal.)

COMMITTEE OF PUBLIC UTILITY.

9. For an apparatus to renew the air quickly in the drying-houses used to oxidise anilin black. (1st class medal.)

PAPER INDUSTRY.

1. For the production and use in France of a white pulp produced by the chemical disintegration of wood. The prime cost of this paper-pulp should be such that it can be used either alone or mixed, and replace rag-pulp advantageously, in white writing paper, or paper for printing of the usual kinds. (Medal of honour and 4000 francs.)
2. For the best essay on the bleaching of rags. (Medal of honour.)
3. For the best essay on the sizing of paper. (1st class medal.)
4. For a method of neutralising or diverting the electricity which is often injurious to the manufacture of paper. (1st class medal.)
5. For a statistical essay on the condition of the paper industry in the principal states of Europe (France, England, Germany, Italy, Prussia, Spain, and Belgium) and in the United States of America. (1st class medal.)

South London School of Chemistry and Pharmacy. Director—Dr. JOHN MUTER, F.C.S.

Hours of Lecture for Session 1872-73:—			
Chemistry (Inorganic)	10 a.m.	Materia Medica	4 p.m.
(Organic)	2 p.m.	Pharmacy	2 p.m.
Botany (Structural)	11 a.m.	Classics (Junior)	9 a.m.
(Systematic)	3 p.m.	(Senior)	4 p.m.

Laboratory open for Practical Chemistry from 10 till 4.

This School affords the most eligible opportunities for obtaining at once a rapid, complete, and practical knowledge of the subjects taught. All the fees are perpetual until the examination in view is passed, without reference to time. Country Students visiting London are placed in Lodgings registered by the Secretary, where no impositions are permitted to be practised, and where the prices are all on a fixed moderate scale. For terms, apply to the Director, or to

W. BAXTER, Secretary.

231 and 285, Kennington Road, S.E.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 726.

THE POLLUTION OF RIVERS' BILL.

WE were all perfectly aware, years ago, that the condition of most English rivers is a danger and a disgrace. Nevertheless, unwilling or unable to trust our own eyesight and our own noses, there was sent out a Royal Commission of inquiry, to whom, for repeating some of the stalest possible truisms have been given—not the proverbial “pinch” due to the bringer of old news. The requirements of red tape having been thus scrupulously fulfilled, we are at liberty to believe that our streams are foul, and to legislate for their restoration to a state of natural purity. Judging from the bill before us there is imminent danger that the remedy may be worse than the disease—that a law may be enacted which will hamper and annoy our manufacturers, give rise to an abundant crop of litigation, and yet decidedly fail to effect the reform desired.

The Select Committee of the Lords appointed to reconsider the first draught of the Bill have sinned against better light and knowledge. In addition to the Reports of the Rivers' Pollution Committee—costly at least, if not valuable—and to its natural appendix, the evidence of Dr. Frankland, they had the independent testimony of Dr. Lyon Playfair; of Mr. J. C. Stevenson, M.P., the representative of the Alkali Manufacturers' Association; of Mr. R. Nichols, an eminent tanner, of Leeds; of Mr. J. Botterill, who may be considered as the spokesman of the Yorkshire dyeing interest; of Mr. R. B. Sanderson, the representative of the coal trade of Northumberland and Durham; of Mr. Ball, Mayor of Newcastle; of Mr. J. Evans, F.R.S., on behalf of the paper trade; of Mr. Crookes; besides other witnesses of less moment. Yet, after hearing this evidence, the Committee have persisted in including as their definition of “polluting liquids”—the entrance of which into any stream is declared penal—the notorious “recommendations” of the Rivers' Pollution Commission! The only modifications adopted, in order to bring these proposals into some little harmony with the necessities of the situation, are the introduction of a clause prohibiting liquids which display a film of petroleum on their surface, and the omission of the clause forbidding all fluids which show a distinct colouration in layers of 1 inch deep, and of the exclusion of any liquid holding in suspension 3 parts by weight of dry mineral matter in 100,000.

The objections against this code, which must by this time be familiar to almost every man of education in the kingdom, have never been faced, least of all by its authors. We have asked—On what principle have the numerical limits fixed in this document been selected? Silence has shown that with the Commissioners and their friends “reasons are not as plentiful as blackberries.” We have shown that the term “organic nitrogen” includes substances highly dangerous, and bodies, like urea, which are no more to be dreaded than pre-formed ammoniacal salts, or than the nitrates and nitrites in the effluent water from an irrigation-farm. No one has come forward to defend the classification we have attacked. We have pointed out that, whilst (Recommendations, §4) arsenic is rigorously excluded, yet copper, lead, and chrome are, by §3, placed on the same footing as such comparatively harmless matters as manganese, iron, and aluminium. To this inconsistency Mr. Crookes, in his evidence before the Select Committee of the House of Lords, called special attention: “There is no difficulty in keeping arsenic out; but it is strange that whilst arsenic is specially provided against, other metals which are almost as injurious, such, for

instance, as copper, lead, and chromium, are allowed to slip through. Those three metals ought to be looked after as sharply as arsenic.” Dr. Lyon Playfair also recommends the exclusion of copper and lead. Yet this advice has been strangely ignored. So strange is the above omission, and so obstinately is it persevered in, that we cannot help pointing to the fact that certain mountain-waters contain traces of copper and lead, and that any very stringent law against the presence of these metals might be hereafter inconvenient to all who wish to force these waters upon the Metropolis.

But without further criticising errors of detail, so open and palpable that those who cling to them have some claim to a place amongst psychological curiosities, let us at once go to the root of the matter. This was pointed out by Mr. Crookes in his evidence: “The bulk of the liquid sent into a river is quite as important as the degree of its pollution. If the river is a tolerably large one a thousand gallons or so of most offensive liquid would be lost in it—it would be of no consequence whatever;—whilst one or two million gallons of a much less impure liquid would really pollute the river more. The bulk of the polluting liquid in comparison with the bulk of the river itself I do not think is mentioned at all (in the Recommendations). There ought to be some stipulation as to the proportion which the polluting liquid should bear to the river into which it flows.”

Again: “Suppose a manufacturer to be situated at the head of the stream, where it is of consequence that nothing shall go in which will in the slightest degree deteriorate that stream, and suppose he throws in a liquid which will not quite come up to these requirements,—the Act can be easily evaded by pumping a little more of the pure river water through his works, thus diluting his liquid down to the proper point and sending that into the river. But exactly the same manufacturer, fifty miles below on the stream, after the river has passed through many towns, and taken the drainage of a large district and of many manufactories, if he throws into the same river the same kind of liquid, will not be able to evade the Act in that way, because the liquid that he would throw into the river would be in some respects purer than the river itself; and he would not, therefore, be able to dilute his waste liquid with a purer water. It appears, therefore, that where the requirements of the Act ought to be carried out stringently evasion would be easy, but where it is of comparatively little consequence to carry out those requirements evasion would be impossible, because the river would be worse than the liquid which was put into it.”

In reply to further questions, Mr. Crookes states: “I would therefore say that no person should send into a river water which is less pure than the water of the river at the place at which it goes in.”

Again: “If the river contained 100 grs. per gallon of impurity, and I turn into it water containing 90 grs. per gallon of impurity, although that is a very impure liquid, I am doing the river good rather than harm.”

This evidence points out the necessity of having, not one hard and fast line for the whole kingdom, but an “elastic test” which will gradually become more and more stringent. Surely that practical common sense, on which Englishmen were wont to pride themselves, will never allow us to punish a man for “polluting” a river when he is actually improving it!

“At Leeds,” says Mr. Crookes, “a manufacturer might dip a bucket into the river, and throw it back again, and he would be in that way throwing water into the river, which would not come up to the requirements of this Act. He might simply pump the river water through his works, without doing anything with it, and he would be liable to be fined.”

To do the Committee of the Lords justice, the absurdity which Mr. Crookes here points out was too great for them to defend, and accordingly in clause 4 of the amended Bill we find the following proviso:—“But no person shall be subject to the foregoing penalties if he proves, to the

satisfaction of the court before whom he is tried, that the pollution caused by him to any river or affluent thereto arises from liquid previously taken by him from such river or affluent, and does not come within the definition of polluting liquid contained in the sixth section of this Act, in a greater degree than when the same was so taken by him." The principle being thus established, we may pardon the illogicality of the expression.

Turning to the evidence of Dr. Lyon Playfair, we find that he, also, perceives the fundamental deficiency of the Bill. He suggests provisions against any discharge into a stream of matters which will raise its sum-total of impurities beyond a certain amount. He thinks it necessary "not only to guard the inlets, but to have power also to look at the stream itself, and to see that it is kept pure;" and he indicates an evil to be guarded against, viz., "the practice of flushing out drains at night, when nobody is there to watch the condition of the water."

This suggestion, like those given by Mr. Crookes, has not been adopted. Indeed, it is easy to see that there is a feeling against them. Dr. Frankland, on his second examination, actually says: "The Bill does not apply to rivers; it is not a Bill to test rivers, but to test the discharges into rivers from factories." Dr. Frankland describes the Bill correctly, and gives the very reason why it ought, as it now stands, to be rejected. His motto is evidently "the recommendations, the whole recommendations, and nothing but the recommendations." Less partial judges, however, will probably look on these same "recommendations" merely as a means to an end, and will reject them as ill-calculated for the attainment of that end. We shall return to the consideration of the remaining evidence given before the Committee, and of the amended Bill as it now stands.

ON THE ESTIMATION OF ALUMINA AND IRON IN PHOSPHATES.

By ALEXANDER ESILMAN.

HAVING had occasion to estimate alumina in various native phosphates and artificial phosphatic liquors during the last twelvemonths, I devised the following process, based on an old method, for the separation of iron and alumina. In its present form I do not claim for it scientific accuracy, but where commercially fair results are required in a very short space of time my past experience warrants me in offering it for trial. It is founded on the fact that, in the presence of an excess of hyposulphite of soda and acetic acid, phosphate of alumina precipitates in the tribasic form ($\text{Al}_2\text{O}_3 \cdot \text{PO}_5$) of constant composition at the boiling temperature. The precipitate is mixed with sulphur, easily washed, and on ignition the sulphur burns off, leaving pure phosphate, 122.5 parts of which are equal to 51.5 parts of alumina. Of course the presence of excess of phosphoric acid must be ensured. All our present methods involve the previous separation of the phosphoric acid, necessitating, in most cases, operating on very small quantities, and delicate working; but the one under notice is applicable whatever be the quantities of phosphoric acid, iron, lime, or magnesia, present. I have, in fact, most commonly used it for determining small quantities of alumina in presence of large proportions of phosphoric acid, where the molybdic method proposed by Ogilvie would be almost impracticable.

One defect of it is the invariable precipitation of traces of iron with the aluminic phosphate, but the following test results, performed under very varying circumstances, show that its accuracy thereby is not materially impaired. The solution ought to be dilute and not very hot, and should contain a tolerable amount of free acid. An excess of hyposulphite of soda is added, then acetic acid in liberal excess. Ten or fifteen minutes are allowed for the complete deoxidation of the iron, and then the solution is boiled for about the same length of time. The

filtration and washing of the precipitate are done hot and rapidly, and, after drying, the latter is ignited in a porcelain crucible.

The iron can be determined in the filtrate from the phosphate of alumina, after decomposition of the hyposulphite, by boiling with excess of hydrochloric acid; but I prefer employing a separate portion for that object. Having experienced an unexpected difficulty in reducing the peroxide by metallic zinc or protochloride of tin, I employ an excess of sulphide of ammonium for that purpose; the excess is decomposed by hydrochloric acid, and the sulphuretted hydrogen is easily and completely driven off by ebullition. This plan is more expeditious than when zinc is used, and more accurate than the tin method.

I have employed this process also for the rapid determination of phosphoric acid in presence of iron and alumina, especially in native phosphates of alumina, and hope to speak favourably of it some day.

ON CONDUCTION OF HEAT IN CRYSTALS.

By the numerous experiments made by De Senarmont in 1847, it was proved that heat is not always propagated, in crystals, at the same rate in all directions. Suppose a centre of heat in the middle of a crystal. If the crystal's symmetry is of the regular system, the iso-thermal surfaces are concentric spheres, but crystals of the dimetric and hexagonal systems conduct equally only in directions perpendicular to the principal axis, so that in such crystals the iso-thermal surfaces are ellipsoids of revolution round the axis; while crystals belonging to any of the remaining systems conduct unequally in all directions, so that in them the iso-thermal surfaces are ellipsoids with three unequal axes.

These results have since been largely treated from the theoretical point of view. An experimental examination

and extension of them has recently been undertaken by M. Jannettaz, who has observed and measured with the greatest care the iso-thermal surfaces in forty-four mineral species, twenty-six of which had not been previously experimented on. The particulars of this research are given in a recent number of the *Annales de Chimie et de Physique*.

M. Jannettaz employed two different methods—One is an improved form of that of De Senarmont, which, it is known, consisted in taking a very thin plate of the crystal to be examined, boring a hole in it, and coating it with wax; a heated rod was introduced into the hole; the heat was conducted through the plate, melted the wax, and thus showed the iso-thermal figure. Of course, the lateral radiation must be prevented by a screen. The improvements by M. Jannettaz are—That instead of wax he used a fat which melted more readily, that the heating arrangement was more suitable, and that for screen he employed a vessel through which flowed a constant stream of water.

In the second method, the boring of a hole in the plate was dispensed with, as it is apt to break the plate. The source of heat consisted of a small platinum ball, to which were connected the ends of two wires from a galvanic battery. The ball was put in contact with the plate; thus the heat-source was reduced to a point, and could be made as weak and as constant as might be desired. The measurement of the axes of ellipses thus obtained was effected by means of a micrometer-screw and telescope.

By these methods, M. Jannettaz obtained, for a large number of substances, numerical values of their conductivity (for heat), which, for these substances, are real characteristic constants; the form of iso-thermal ellipsoid is thus a characteristic indication of the mineral species. In the optical uni-axial crystals, the ellipsoid is sometimes flattened, sometimes drawn out in the direction of length. The latter is the case in quartz, whose ellipsoid is comparatively very long. The proportion of the axis to the radius of the equator is in this ellipse 1.312. It deserves to be noticed that this number is exactly the same as that obtained by De Senarmont, a proof of the great experimental exactness of this experimenter, who wrought with very imperfect instruments. Calc-spar shows also a lengthened ellipse, the proportion between the two axes, however, not exceeding 1.095. Antimony, on the other hand, gives a very oblate ellipse; the radius of the equator is to the axis of rotation as 1.59 to 1. Among the optical bi-axial crystals, mica gives the most distinct ellipsoid, but its appearance varies in pieces from different localities. In the clino-rhombic system, gypsum is well fitted for such experiments, and gives a very distinct ellipse.

Through these measurements, which in themselves, and apart from any theory, are advantageous, as giving new specific constants for a determinate number of mineral species, M. Jannettaz believes he has been able to furnish proof that a common relation exists between the lines of greater and less conductivity and the directions of cleavage. Consider the uniaxial substances. The conductivity is less in the direction of the axis in species with basal cleavage, greater in species with prismatic cleavage. If the cleavage follows the rhombohedral surface, and if the angle which it makes with the principal axis is greater than 45° , the cleavage must be reckoned prismatic; when, on the other hand, the angle is greater than 45° , the cleavage is basal. The theoretical meaning of this law is that heat is better propagated in the direction parallel to the surface of cleavage, than in the direction at right angles to it.

This law is verified for the greater number of substances which were experimented with; a remarkable exception from it, however, is met with in emerald and calc-spar, which, from the nature of their cleavage surfaces, should belong to the class of substances with flattened ellipsoids, and which yet give an elongated ellipsoid. M. Jannettaz calls to mind that, according to M. Fizeau, these two substances, on elevation of temperature, show a contraction in the direction of one of their axes.

For the other crystal systems the law is in general

proved, and particularly in the case of mica and gypsum. With both these substances, M. Jannettaz, by boring a hole through them, obtained coloured ellipses, produced from a thin layer of air which penetrates between two laminae of the substance, their axes corresponding to the thermal axes. In gypsum, which has two unequal surfaces of cleavage at right angles to the easy direction of cleavage, the long axis of the ellipse is, according to M. Jannettaz, a direction of least cohesion, arising from the union of two directions of cleavage; the production of the coloured rings, and the coincidence of their axes with those of the iso-thermal curves thus proves the law.

M. Jannettaz further states his intention to investigate several other questions connected with this subject; especially the hypothesis on crystals enunciated by Bravais, and also the result of De Senarmont's experiments with compressed glass, in which he obtained an iso-thermal ellipsoid with its small axis in the direction of compression.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BRADFORD MEETING, 1873.

SECTION B.—CHEMICAL SCIENCE.

PRESIDENT, DR. W. J. RUSSELL, F.R.S.

(Continued from p. 198).

"An Improved Form of Gas Generator," by C. J. WOODWARD, B.Sc.

The author referred to various arrangements which had been devised for readily bringing into juxtaposition, or removing from each other, the material required to generate a gas, but stated he did not feel satisfied with any of them, and sought in the apparatus he had made to overcome the objections experienced. Two forms of apparatus had been made. The first, shown in section in Fig. 1, and

FIG. 1.

intended for large supplies of gas, consists of a circular stoneware vessel, A A, holding 3 or 4 gallons, and surmounted by a large cylindrical pipe, B. In the top of the vessel is a tubulure, C, to which is fitted a glass cylinder containing the granulated zinc or other gas-generating

material. To the opening of the upper end of the glass cylinder is attached a cork and the delivery tube, D. A plug, E, can be raised or lowered by means of a cord, which, passing over pulleys, terminates in a ring, F. It will readily be seen in what way the apparatus is used. As seen in the figure, the plug, E, is immersed in the acid, with which the stoneware jar is filled, and the liquid has risen by displacement into the glass cylindrical vessel coming in contact with the gas-generating material, when of course the evolution of gas goes on. When it is desired to stop the flow of gas, the plug, E, is raised, the ring, F, being slipped over the stud, G. The acid now retreats from the glass cylinder, and the gas-generating material is left dry. At any time, then, when gas is wanted, it is only necessary to release the ring, F, the plug, E, falls into the acid, the zinc, marble, &c., becomes covered, and the flow of gas begins and can easily be arrested in the manner first described.

The second form of apparatus, used when only a small supply of gas is wanted, consists of a Wolff's bottle, A, Fig. 2,

FIG. 2.

to one tubulure of which is fitted a cork carrying a glass tube and piece of caoutchouc piping, B. This pipe, B, can be closed by a pinch-tap, C. To the other tubulure of the Wolff's bottle is fitted the adapter, D, in which is placed the zinc, marble, or other gas-generating material. To the upper end of the adapter is fitted a cork and tube, E, serving for the escape of gas which is washed at F, and then passes on for use. To use the apparatus, the Wolff's bottle is charged with acid up to the level indicated in the figure. Then, on blowing air by the mouth by means of the tube, B, the pinch-tap, C, being open, acid is forced into the adapter, D, and gas at once comes off. The pinch-tap, C, is now closed, and the compressed air in the Wolff's bottle still keeps the acid in the adapter. When it is desired to stop the flow of gas, the pinch-tap, C, is opened, the compressed air escapes, and the acid in the adapter falls, leaving the gas-generating materials dry. Should the blowing of air by the mouth be deemed objectionable, an air-ball may be attached to the pipe, B. A safety-tube, C, is used, in order to prevent the liquid from the wash-bottle being drawn over on stopping the supply of gas.

Professor SCHAFARIK, from Prague, read a "Note on the Constitution of some Natural Silicates," namely, those in which chlorine and fluorine enter as essential constituents. They are few in number, but some of them important—as mica, tourmaline, topaz; others interesting for their rarity, as cucalyte, pyrosmalite, tencophane; or for their mode of occurrence—as sodalite. According to modern chemical views these minerals were, Dr. Schafarik said, considered as silico-fluorhydrides and silico-chlorhydrides—namely, as silicic hydracids, in which a part of hydrogen is replaced by metals, another part by a polyvalent metal only partially saturated by chlorine or fluorine. The formulæ of these substances were discussed at length, and graphi-

cally constructed, showing the most simple and probable manner in which the single atoms might be arranged. The most interesting results are those found for topaz, chondrodite, and tourmaline. The first is remarkable for the simplicity and beautiful symmetry of the new formulæ, when compared with the unwieldy old ones. The other two mineral species are remarkable for variability of composition, which perplexed older chemists. The author shows that both are formed by the repetition of pretty simple fundamental molecules, which are linked together in any number like chains. In the case of chondrodite, the chain is open, as in fatty organic bodies; in tourmaline, it is closed, as in aromatic compounds. Only in carbon compounds the carbon atoms themselves are linked together; in silicates the fundamental molecules are linked together by atoms of oxygen.—Experiments for testing these theoretical results are in progress.

Professor LAWRENCE SMITH, of America, congratulated Dr. Schafarik on having taken the true direction in the study of silicates. Hitherto they had been labouring under great difficulty in the study of these substances, from the fact that they had had to proceed on very incorrect data. Their analyses of natural silicates were very imperfect. It would be necessary to introduce into the study of silicates the same system as was employed in the study of organic chemistry. Silicon would be found to resemble, he believed, in the mineral kingdom in a great many of its properties, carbon in its relations in the organic kingdom. If the study were pursued in the direction which had been indicated, he believed a great deal of light would be thrown on silicates.

Dr. CRUM BROWN dwelt upon the importance of distinguishing between mineral structural formulæ and organic formulæ, and said that Dr. Schafarik had advanced in the right direction in the grouping and classification of these minerals which he had adopted.

The PRESIDENT (Professor Russell) said the section was much indebted to Dr. Schafarik for the paper he had brought before the Section, and for pointing out the relationship between organic and inorganic chemistry, and applying to the latter the modes of reasoning and thought which had been developed in the former. In the organic branch they had fortunately got compounds which they could with comparative ease experiment with. He hoped that before long they would get a great deal more power over the silicon compounds than they had. There was some reason for believing that they might be able to build up minerals and decompose them with much greater facility at all events than they could at present.

Mr. A. H. ALLEN, F.C.S., followed with a paper "On the Detection of the Adulteration of Tea." He said that, as public analyst for the borough of Sheffield, many samples of tea had been brought under his notice, chiefly by dealers themselves, in order to guard against selling tea, which, if they had been analysed by him officially, might have been condemned as adulterated. The analyses of tea up to the present time were by no means numerous; and some were so old that they might well be viewed with suspicion. The three principal constituents of tea were tannin, gum, and "woody fibre," with small quantities of some albumenoid body, theine (the active principle), colouring matters, chlorophyll, essential oils, &c. The proportions of these found by different analysts varied very much, the difference evidently depending upon the methods of determination employed. His object had been more to work out a technical method of testing teas for adulteration than to establish the actual composition of genuine tea. The estimations that had been made of tannin seemed to present the greatest variations, and in many cases they were manifestly wrong. A modification of Dr. Hassall's process, in which a volumetric solution of gelatin was used, had given him very concordant and reliable results, and had made the determination of tannin in tea an operation of a rapid and tolerably simple character. The use of a standard solution of gelatin for the determination of the strength of tannin

matters was nothing new; but he believed he had been the first to employ the process in the examination of tea. Mr. Allen then described the details of the method he employed in the estimation of tannin, stating that he had found by the process in genuine black tea of rather more than average quality 12.5 per cent of tannin, which presented a close agreement with those in the old analyses of Mulder, which he regarded as the most accurate and complete analyses of tea extant. The estimation of tannin was of the first importance; for if it reached the normal amount all question of adulteration by exhausted leaves was at an end, and foreign leaves were very unlikely to be present. The only fallacy in such a conclusion would be caused by an admixture of catechu, or aloe leaves. The next point of importance was the percentage of "woody fibre," as it was called by some analysts, and here, again, he was disposed to think that Mulder's analysis was the only accurate one. The percentage of gum, insoluble matter, and tannin in any sample of tea, considered carefully, would enable the analyst to form a very accurate opinion as to the presence or absence of exhausted leaves, &c. Analysed by the above described methods a sample of very superior black Congou tea gave the following results, which he had placed in juxtaposition with the numbers obtained after some of the same sample had been infused in the usual manner in the teapot (the exhaustion was not carried to excess, no second quantity of tea being used), and the leaves re-dried:—

	Original Tea.	Exhausted Tea.
Moisture	9.2	11.1
Insoluble matter .. .	58.7	87.5
Gum	10.5	3.8
Tannin (by gelatin) .. .	15.2	3.3

From this it would be seen that infusion in the teapot resulted in the increase of the insoluble matter by nearly 30 per cent, while the gum and tannin were much reduced in amount. Generally the exhausted leaves were re-dried and made up with gum, which gave them a peculiar glossy appearance, and was detected by excess on analysis. From a table which he had prepared of thirteen different analyses, he gave several instances of adulteration. In one case he was attracted by a table in a window, "Try our fine rough, flavoured, thick, sappy, Moning Congou at 2s. a lb." The specimen, when examined, was found to contain catechu, starch, magnesia, metallic iron, graphite, sand, &c. He had also found aloe leaves presenting a close resemblance to green tea in every respect. An inspection of the specimens analysed showed that genuine green teas were richer in tannin than black teas in about the proportion of two to three. This was no doubt due to the partial oxidation and destruction of the tannin during the process of fermentation to which black tea is subjected in the process of manufacture. Whether the acknowledged superior strength of green tea was due to the larger percentage of tannin present in it, he was not prepared to say. The determination of theine he had made did not account for the difference, and most analysts had found more theine in black than in green tea. The infusion of green tea was not nearly so strong in colour as that of black tea, though it was half as strong again in tannin, so that the depth of colour could not be regarded as a proof of strength, though generally so considered. If a solution of carbonate of sodium be added to a weak infusion of tea (strained away from the leaves) a considerable darkening was observed, though certainly the infusion could become no stronger. Thoroughly extracted tea leaves yield a brown liquid when treated with carbonate of sodium solution. These facts quite explained why careful housewives had a fancy for putting soda in the teapot, the infusion becoming sensibly darker by the addition, to say nothing of the extra colouring matter from the leaves. Apart from its softening effect on the water (the advantage of which he thought was doubtful), there could be no good reason for its addition.

In the methods he had used for detecting facing and colouring there was not much that was new. On treating the tea with warm water the colours and facings came off, and on straining off the leaves and leaving the liquid at rest, they gradually settled to the bottom. If prussian blue or indigo were present the sediment generally had a bluish or greenish colour, and the tests for these pigments must be tried accordingly. Magnesia was often present both in the free state and as insoluble silicate. This latter facing he had found on several occasions lately on green teas of peculiarly smooth appearance and slippery feel. It was detected by heating the sediment with hot hydrochloric acid, and then with solution of caustic soda. The residue was ignited and fused with alkaline carbonate, the first product dissolved in acid, evaporated to dryness, re-dissolved in weak acid, the solution treated with ammonia and oxalate of ammonia, the precipitate filtered off, and the clear liquid tested in magnesium, in the usual way, by phosphate of sodium, when an abundant precipitate was obtained, proving the presence of magnesium as silicate.

The PRESIDENT observed that the Adulteration Act would no doubt have the effect of increasing the number of chemists in England, and such questions as that of the adulteration of tea would day by day become more important. He wished that a great many of the analysts appointed under the Act would follow Mr. Allen's very good example, and bring to the Association the results of their experiments. Mr. Allen had worked out the case of tea very thoroughly, and at the same time he had shown some of the pitfalls into which chemists were pretty sure to tumble sooner or later. There was a great deal to be done in these testings for adulteration, and to make the Act in any way useful the testings must be carried out in a most thorough and accurate way. He only wished all public analysts were as careful as Mr. Allen.

Mr. CAIL asked Mr. Allen whether he had made any analysis of the ash of the tea plant?

Mr. ALLEN said he had not; but that the ash should not exceed more than 5 per cent. Many of the things used for adulterating tea had more.

Mr. CAIL said he had made analyses, and found a good deal of manganese in the tea. He desired to know whether that was used for colouring, or whether it was got out of the soil by the growth of the plant. It might be used as a colouring in preference to prussian blue.

Mr. ALLEN said that manganese was understood to be one of the constituents of the ash of the tea; and added that he thought foreign leaves might be more easily detected by skeletonising the leaves than by simply putting them under the microscope.

"Specific Gravity Bottle for Liquids Spontaneously Inflammable in contact with Air," by ALFRED TRIBE.

The bottle usually employed for sp. gr. determinations of liquids consists, essentially, of a light flask provided with a perforated stopper. By means of this arrangement sufficiently accurate results can be readily obtained when the liquid is not very volatile or violently acted upon by the air.

To meet the requirements of volatile liquids, Regnault employed a flask having a solid in place of a perforated stopper, and a neck somewhat longer and narrower than the old form. The liquid is poured up to a mark made on the neck, and the water value being known, the specific gravity is found. It is obvious that by this method loss by evaporation or expansion during weighing is prevented. For liquids, however, which are violently decomposed by the air, especially when with formation of thick clouds, e.g., the zinc compounds of the lower members of the alcohol radicals, this plan, from the practical impossibility of adjusting with accuracy to the given work and the required temperature, is not so satisfactory as might be desired.

To meet liquids of this class I have devised the following improvement upon Regnault's bottle:—The neck is of as even bore as possible, and divided into as many equal

parts as can be conveniently read. The bottle (made by Cetti) actually employed, which answered perfectly, has a capacity of 2.6 c.c., the neck being about 3 m.m. internal diameter and 13 long, divided into $\frac{1}{4}$ m.m. Just beyond the graduations the neck is widened somewhat for the stopper and for pouring in the liquid.

When once the water values have been determined for each division on the neck, it will be seen that it is only necessary to fill the bottle so that the surface of the liquid shall fall within the range of the graduations. Another advantage is that the contents can be raised or lowered to the normal temperature, and the volume read off, without addition or subtraction of liquid.

The $\frac{1}{4}$ m.m. divisions of water weighed 5 milligrams. As it is easy to read to a half of one of these divisions, and, with care, to a quarter, the error need not be more than the weight of liquid equal to one or two milligrams of water. A pipette with a capillary tube will be found convenient for introducing the liquid, and of course the operation of filling liquids of the character of zinc-ethyl should be done in absence, as far as possible, of free oxygen.

CORRESPONDENCE.

COPPER IN FEATHERS.

To the Editor of the Chemical News.

SIR,—In connection with a letter published in your last number, the following observations, made three or four years ago, may interest some of your readers:—

We kept at that time two Australian love-birds of the variety called *Melopsittacus undulatus*, small parakeets, with grass-green plumage. The birds were often allowed to fly about the room, and I observed that they preferred brass fittings to any other perch, and that they used to sit and peck at the brass-work. On asking an Australian friend as to the habits of these birds, he told me that they abound chiefly in the districts where copper is found.

These facts, and the recollection of Mr. Church's discovery of copper in the red feathers of the turaco, led me to examine some of the feathers which these birds had let fall in flying about.

I collected seven or eight of the feathers, burnt them, and extracted the residual ash with nitric acid. On adding solution of potassium ferrocyanide to the filtrate, a distinct precipitate of the colour of copper ferrocyanide formed.

The cage in which the birds lived was of iron, not brass, wire; and as we had already had them more than a year, and they were in the habit of frequently washing themselves, it seems certain that the copper found in the ash existed naturally in the feathers.

Probably a green pigment, analogous to Mr. Church's turacin, of which copper is a constituent element, may be extracted from these feathers. My attention having been recalled to the subject by your correspondent's letter, I propose to examine it further.—I am, &c.,

Christ Church, Oxford,
October 18th, 1873.

SYDNEY LUPTON.

MANUFACTURE OF GAS.

To the Editor of the Chemical News.

SIR,—I am manufacturing gas upon my patent system of carbonising, which is done by passing the hydrocarbons

over incandescent coke, therefore making more pitch than tar. The gas and pitch come into contact with water as they leave the retort; the result is that a green and a yellow-green colour is washed out of the pitch (which I take to be anthracen), the colour varying according to the quality of coal carbonised, when, after long exposure to light, it becomes black (oxidised), which resembles the sediment of black ink. Would you or any subscriber say if it is worth collecting?—I am, &c.,

A. MALAM.

Dumfries, Oct. 21, 1873.

NEW VOLUMETRIC ASSAY OF IRON.

To the Editor of the Chemical News.

SIR,—Many chemists will sympathise with Captain Ross in his protest against the shortcomings of discoverers (?) who publish as new facts processes so long since made public; but, with reference to the special grievance of the gallant captain, if he takes the trouble to refer to his letter to the CHEMICAL NEWS, vol. xvii., p. 23, he will see that, although he therein suggested the idea that ferric sulphocyanide might be used as an indicator in the well-known process of determining the combined acid in a metallic salt (such as a per-salt of iron) by means of a standard alkaline solution, he yet had not at that time carried out his idea to a practical result; and, moreover, that he took no account of the fact that all free acid must be absent. Now M. Charpentier, whom Captain Ross accuses of injustice, has at any rate these merits—that he made the process work (more or less accurately), and that he took cognisance of that latter very material circumstance.

In the letter referred to, Captain Ross solicited the opinion of chemists on his ideal process; in answer to his request, I pointed out—Firstly, that the process, as suggested by him, would give inaccurate results, from the necessary presence of free acid; secondly, that it is impossible to estimate accurately the amount of free acid in such in solution by the ordinary volumetric processes; and, thirdly, that the decolorisation of ferric sulphocyanide (and also of ferric ferrocyanide) is a less sharp terminal reaction than the change of colour in certain vegetable colouring matters. It may therefore be inferred (as is proved by actual experiment) that the Ross-Charpentier process is less convenient in practice than those in ordinary use.—I am, &c.,

C. R. A. WRIGHT, D.Sc.

Chemical Laboratory, St. Mary's Hospital,
Paddington, W., Oct. 22, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 22, 1873.

On Corallin.—M. Commaillé.—Corallin is obtained at temperatures which may vary from 115° to 150°, at the latter temperature the yield is more considerable and the operation more rapid. The quantity of oxalic acid recommended by authors is far too high. Corallin does not give definite metallic salts, but merely coloured lakes. Yellow corallin is not an acid, for it does not expel carbonic acid from its combinations, and does not form

definite compounds with bases. The name of rosolic acid applied to it is quite incorrect. Red corallin does not contain nitrogen, and cannot therefore be an amide of the red variety.

Thermal Researches on the Condensation of Gases by Solid Bodies (Continued); Absorption of Hydrogen by Platinum Black.—M. Favre.—When hydrogen is brought in successive portions into contact with platinum-black up to saturation, the heat liberated is not constant for equal weights of gas absorbed, as in the case with palladium. Thus, in condensation of ordinary gaseous hydrogen by platinum, the first experiment gave 23,075 calories; the fourth, 13,528. Hydrogen condensed by palladium seems to be distributed in a uniform way throughout the metal, forming with it a true alloy; whereas hydrogen condensed by platinum-black is apparently distributed like carbonic acid or ammonia fixed by wood-charcoal, *i.e.*, forming layers less and less dense, from the surface of the metal inwards. It is a phenomenon of *capillary affinity*. It is likely that, as in the case of sulphurous acid and protoxide of nitrogen condensed by wood-charcoal, the heat liberated exceeds the latent heat of liquefaction of the gas. The author next considers what occurs in the electrolysis of sulphuric acid, *e.g.*, with a couple of zinc and palladium (Expt. I.), and one of zinc and palladium (Expt. II.). In the former case the gas is fixed in the active state by the palladium at the moment of leaving, the liquid and the 9000 calories or so liberated in fixation are the thermic expression of the condensation; in which the gas has passed to the *solid state* without ceasing on that account to be active. In the case of zinc and platinum, however (Expt. II.), the active hydrogen, issuing in the state of a true explosive substance, undergoes an allotropic modification, and is transformed into ordinary and liquid hydrogen. In this transformation, notwithstanding absorption of heat through passage of the hydrogen, thus formed from the liquid to the gaseous state, the calorimeter shows about 4600 calories. Recurring to the condensation of ordinary gaseous hydrogen by platinum, it appears that the hydrogen active and liquid (*i.e.*, existing in the liquid compound from which it is separated), which liberates about 4600 calories in passing to the ordinary gaseous state, and about 20,700 calories in being fixed by platinum-black after this transformation, would liberate about 25,300 calories if it did not undergo a transformation before its condensation by platinum, at the surface of which it ceased to be in the active state. Another conclusion is that the active and liquid hydrogen, which liberates only about 9000 calories, in being fixed directly by the palladium (Expt. I.) must necessarily, remaining active, constitute with this metal a true explosive alloy, susceptible of liberating about 14,000 calories by decomposition into palladium and ordinary hydrogen, supposed in the solid state. From these and other thermal phenomena studied it seems well established that the hydrogen entering into the formation of acids is in the active state, and M. Favre thinks the same may be said of the hydrogen in water. The thermal phenomenon of the formation of water, and that of its decomposition are not, he remarks, so simple as might at first be supposed. Starting with the constituents of water, taken in the ordinary state, the quantity of heat shown by the calorimeter is the algebraic sum of the numbers furnished by the following phenomena:—(1) Passage of hydrogen and of oxygen, ordinary and gaseous, to the active and also gaseous state; (2) combination of these elements thus modified; (3) passage of water vapour to the liquid state.

Some Peculiarities Relative to the Winged Form of Phylloxera, as Regards Propagation of the Insect.—M. Cornu.—The author arrives at the conclusion that the winged individuals of *Phylloxera vastatrix* are much more numerous than has hitherto been thought: that they use their long and fragile wings (as the *Phylloxera quercus* also does), and with the aid of wind may be carried

a considerable distance. The observation has an important bearing on the choice of remedies.

The Most Suitable Time to Apply Submersion to Vines Tainted by Phylloxera.—M. Faucon.—The author states objections to submersion in either spring or summer.

Integration of Equation with Partial Derivatives for Isostatic Cylinders Produced within a Mass Subjected to Strong Pressures.—M. Boussinesq.

Movement of an Elastic Wire, one Extremity of which is Animated by a Vibratory Movement.—Second note by M. Mercadier.—An eighth law is added for the normal vibratory state, *viz.*, that for different wires of the same section the normal nodal distances are proportional to the fourth roots of the quotients of the coefficients of elasticity divided by the density. Coming to the *abnormal* vibratory state, the author describes the phenomena obtained on shortening the wire, millimetre by millimetre, beginning with the normal state. The vibrations become curvilinear, and this amplitude increases, while that of the diapason diminishes, and may even become *nil*. On further shortening the same phenomena are reproduced, but in reverse order; till the normal state recurs, the vibrations of the wire becoming plane. The author constructed two curves, having for abscissæ the lengths of wire, and for ordinates of the one the amplitudes of the free extremity of the wire; for those of the other the amplitudes of the diapason. The following laws are deduced:—(9) The lengths of wire for which the amplitude of the free end is minimum and equal to that of the diapason are, commencing with the shortest, in arithmetical progression, the ratio of which is precisely the normal nodal distance of the wire. (10) The lengths of wire corresponding to the points of complete extinction of the diapason are also, commencing with the shortest, in this arithmetical progression. (11) Each of the points corresponding to minimum amplitude of the wire is very nearly at equal distance from the two points of extinction of the diapason, between which it is comprised. The foregoing research has a practical bearing on the question, *viz.*, what length to give a style fixed to the end of a vibrating body (tuning-fork, *e.g.*), so as to have the greatest amplitude possible without altering the vibratory period of the diapason. The abnormal vibratory state must evidently be avoided.

Proportion of Carbonic Acid in Atmospheric Air; Variation of this Proportion with the Altitude.—M. Truchot.—The observations were made almost daily during July and August at Clermont Ferrand. The method consisted in passing the air into baryta water previously titrated, then allowing deposition of the carbonate formed, then titrating anew the limpid supernatant liquor, a known quantity of which was separated with a pipette. The numbers obtained show—(1) That the proportion of CO₂ is a little greater during the night than during the day (as was previously observed by De Saussure and Boussingault). (2) That the proportion is not sensibly higher in the town than in the country. (3) That in the neighbourhood of plants with green leaves in full vegetation the proportion of CO₂ varies considerably according as these green parts are illuminated by the sun, or are in shade, or quite in darkness; this agrees with a well-known fact in vegetable physiology. (4) That, on a general average, the proportion is 4.09 vols. per 10,000 vols. of air, which closely agrees with the numbers obtained by De Saussure (4.15); Thenard and Boussingault (4); and Verver (4.2); but is much higher than those of German observers, Schulze (2.9), and Henneberg (3.2) at Rostock and Weende. To ascertain the influence of height, determinations were made simultaneously at Clermont Ferrand, 395 metres above the sea; at the top of Puy du Dôme, 1,446 mètres; and at the top of Lancy, 1,884 metres. The respective numbers were 3.13 vols. (per 10,000 of air), 2.03, and 1.72; showing a marked decrease with the height. This is not surprising when one

considers that, on the one hand, it is at the surface that CO_2 is produced; and, on the other, that it is considerably heavier than air.

Observation, on the Night of Sept. 20, 1873, of a Bolide which left behind an Incandescent Train.—M. Chapelas.—The train, observed through a telescope, presented a remarkable undulation. It continued ten minutes after the complete disappearance of the meteor, having the same direction. Then, becoming more compact and brilliant, it suddenly took the direction of the wind, N.W. to S.E. (being originally N.N.W. to S.S.E.). A very thick mist covered Paris immediately afterwards.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., No. 5, October 2, 1873.

Transparent Paper.—The paper is soaked in the following composition—Linseed oil, boiled and bleached, 20 kilos.; lead turnings, 1 kilo.; oxide of zinc, 5 kilos.; Venice turpentine, $\frac{1}{4}$ kilo. The whole is mixed and boiled for eight hours; after cooling it is stirred, and the following ingredients added:—White copal, 5 kilos.; and sandarac, $\frac{1}{4}$ kilo.

Poisonous Nature of Cobalt.—According to Siegen the nitrate and chloride of cobalt rank among poisons. 1 centigram. of either of these proved fatal to a frog in half-an-hour; 3 decigrams. killed a strong rabbit in three hours. The poison acts directly upon the muscles of the heart.

Indelible Ink.—Elsner takes equal parts of copperas and vermilion, powders, sifts, and grinds with linseed oil; the whole is finally pressed through linen. The thick paste can be applied for writing and for printing on wool or calico. It resists bleaching.

Revue Scientifique de la France et de l'Etranger,
September 12, 1873.

Meeting of the French Association for the Advancement of Science at Lyon.—*Chemical Section*, August 25.—Ch. Blondeau—proceeding on the theoretic idea that sugar introduced into the animal organism can be transformed into alcohol and carbonic acid by the action of the blood globules playing the part of a ferment—brought blood and glucose into contact and obtained alcohol, the nature of which he verified by taste; smell, and by its reaction with the permanganate of potassa. Hence he infers that there occur in the system phenomena of fermentation calculated to split up sugar into alcohol and carbonic acid. The fermentation of sugar under the influence of blood has been confirmed by M. Béchamp.

M. Balard remarked that the characteristics adduced by M. Blondeau were insufficient to prove the presence of alcohol.

M. Wurtz pointed out that the procedure of Gay-Lussac (repeated distillation over carbonate of potassa) rendered it practicable to isolate very small quantities of alcohol, and that the presence of this body could be demonstrated by transforming it into iodide of ethyl.

M. Friedel gave a summary of the researches which he had carried on in concert with M. Silva on pinacol, $\text{C}_6\text{H}_{14}\text{O}_2$, obtained by the hydrogenation of acetone. He explained the most advantageous method of preparing pinacol, and described the action of perchloride of phosphorus upon this compound. Perchloride of phosphorus acts upon pinacol, a tertiary glycol, not by forming the normal chloride $\text{C}_6\text{H}_{12}\text{Cl}_2$, but a chloride, $\text{C}_6\text{H}_{11}\text{Cl}$, representing the normal chloride, less a molecule of hydrochloric acid. At the same time the perchloride exerts a chlorinising action upon $\text{C}_6\text{H}_{11}\text{Cl}$, producing in the same reaction a crystalline body, $\text{C}_6\text{H}_{10}\text{Cl}_2$. These two chlorides, $\text{C}_6\text{H}_{11}\text{Cl}$ and $\text{C}_6\text{H}_{10}\text{Cl}_2$, are not saturated, as they can fix 2 atoms of bromine yielding respectively $\text{C}_6\text{H}_{11}\text{ClBr}_2$ and $\text{C}_6\text{H}_{10}\text{Cl}_2\text{Br}_2$. To obtain the normal chloride, $\text{C}_6\text{H}_{12}\text{Cl}_2$, it is necessary to have recourse to the less violent action of oxychloride of phosphorus upon pinacol, or to that of

the perchloride of phosphorus upon pinacol, $\text{C}_6\text{H}_{12}\text{O}$. The chloride, $\text{C}_6\text{H}_{12}\text{Cl}_2$, crystallises and is identical with the bichlorated di-isopropyl described by M. Silva.

MM. Friedel and Silva have also studied the action of nascent hydrogen, and that of oxidising agents upon pinacol. By hydrogenation two compounds are obtained; a crystallised body resulting from the fixation of 2 atoms of hydrogen upon 2 molecules of pinacol, and containing $\text{C}_{12}\text{H}_{26}\text{O}_2$, and pinacolic alcohol, $\text{C}_6\text{H}_{14}\text{O}$. Of this alcohol the authors have prepared the iodide, the acetate, and the benzoate. On oxidation it reproduces the pinacol. The oxidation of pinacoline gives rise to pivalic acid, $\text{C}_5\text{H}_{10}\text{O}_2$, isomeric with valeric acid, crystalline, and fusible at 30° . This acid appears identical with the trimethyl-acetic acid of Boutlerow.

M. D. Tomasi has been occupied with the action of the chloride of chloracetyl upon various primary monamines of the aromatic series. He has obtained chloracetanilide, $\text{C}_6\text{H}_5\text{NHC}_2\text{H}_4\text{ClO}$, chloracetyl-toluidin, and chloracetyl-naphthylamin. He described also chloracetyl-urea.

Ch. Risler gave a summary of the most recent analytical applications of the hydrosulphite of soda.

MM. Schützenberger and Risler have applied the reducing power of this salt to determine oxygen dissolved in water and in blood. M. Risler described the apparatus employed in these determinations.

MM. Schützenberger and Quinquand have applied the same reaction to study the respiration of submerged aquatic vegetation, and to ascertain the action of beer-yeast upon dissolved oxygen.

SESSION OF AUGUST 27th.

M. A. Henninger has studied the reducing action of formic acid upon alcohols of different atomicities.

M. Wurtz, having obtained the normal density of the perchloride of phosphorus by allowing it to diffuse in one of its products of dissociation, the protochloride of phosphorus, attempted to find the normal density of the hydrochlorate of ammonia by an analogous procedure. He caused this salt to diffuse in hydrochloric gas, but ammoniac volatilises at a very elevated temperature, at which it becomes entirely dissociated in spite of the presence of hydrochloric gas. The density yielded by experiment in these conditions corresponds to four volumes of vapour, that is, to a complete dissociation of the salt into hydrochloric acid and into ammonia. M. Wurtz called attention to the generality of the phenomena known as dissociation.

M. G. Loremoine described the transformation of white phosphorus into the red state, and the curves of dissociation of hydriodic acid.

M. Ribau explained his interesting researches on the terebic carbides, and the isomerism of their hydrochlorates.

M. Gourdon, of Lyon, described some novel facts which he had observed in the action of acids upon zinc covered with certain metals. Zinc plunged into dilute solutions of sulphuric, hydrochloric, and acetic acids is attacked only at the points where other metals are present. The metals which produce this phenomenon with most intensity are cobalt, platinum, nickel, and iron. Ammoniacal chloride of cobalt renders it possible to perforate zinc with water containing only 1-10,000th part of sulphuric acid. M. Gourdon applies these results to various procedures for engraving. By writing directly upon zinc with different metallic inks, making use of the most active, containing salts of cobalt for the blackest parts, and passing it then into acidulated water, an engraved plate is obtained. To reproduce leaves or plants they are soaked in solutions of metallic salts, and applied to the zinc, which is then treated with weak acid. The author has discovered a new kind of heliographic engraving by transferring the silver from an ordinary photographic proof upon the zinc, which can be attacked by the acids in the parts where the silver has been deposited.

M. Vidal described his process of polychromic photography.

M. Vignon has prepared mannitan by mixing mannit with half its weight of concentrated sulphuric acid, and keeping the mixture at 125° for two hours. Mannitan turns the plane of polarisation to the right, and does not yields mannit even on boiling with baryta water for an hour. If mannit is heated to 280° with a little water a body is obtained which appears to be mannitan, but which turns the plane of polarisation to the left, and yields mannit on boiling with water.

M. Vignon has likewise examined the action of sodium amalgam upon ammoniacal salts, and determined the conditions under which the greatest quantity of the ammoniuret of mercury is produced. The sodium amalgams are less efficacious the more sodium they contain. With nitrate of ammonium sodium amalgam does not yield an ammonium amalgam. There is a brisk effervescence due to the escape of nitrogen. In fact if nitrate of potassa is treated with sodium amalgam, nitrogen is evolved, and nitrite of potassium formed. As sodium amalgam does not act upon the compound ammonias, M. Vignon proposes the use of this amalgam to detect the presence of ordinary ammoniacal salts in the salts of the compound ammonias.

M. Grüner has been engaged with measuring the quantity of heat needful to effect the fusion of cast-iron slags, dross, and steel, in order to compare the heat produced in blast-furnaces with the heat utilised. He finds that cast-iron melts at from 1579° to 1462°. Bessemer steel melts at 1600°.

SESSION OF AUGUST 28TH.

M. Masson, of Lyon, exhibited various specimens of veterinary medicines.

M. Perret exhibited hydrochlorate of trimethylamin obtained from herring-brine, anthracen, valerianate of quinine obtained by the double decomposition of sulphate of quinine and valerianate of baryta, slightly basic.

M. Jacquemin's paper "On the Analytic and Toxicological Detection of Phenic Acid" was read. The reaction upon which the author's method depends is the blue colouration produced by hypochlorite of soda in a mixture of phenol and anilin. It was remarked by several members that anilin alone gives a blue reaction with alkaline hypochlorites.

M. Macé sent in a memoir on the existence of germ ferments in living organisms. He maintains that germ ferments may exist for a time in the organism in a passive state.

No. 13.

Photometry of Absorption Spectra, and its Application to Quantitative Chemical Analysis.—Ch. Vierordt. —This paper, translated from the German, is not suited for abstraction.

No. 14.

This number contain no chemical matter.

Reimann's Fürber Zeitung, No. 33, 1873.

This number contains receipts for green, crimson, and yellow on shoddy, and ponceau on cloth, and for blue and brown on silk.

In reviewing the Vienna Exhibition, the beautiful sugar-of-lead and yellow prussiate in the Austrian department are spoken of as far surpassing any similar articles from the German Empire. Joseph Nowak, of Prague, exhibits starch in all preparations, flavin, and lake colours, especially a cochineal ponceau, and a fustic lake ready for direct application in calico- and woollen-printing. It is remarkable that Austria has not a single manufacture of anilin and anilin colours; this is ascribed, in part, to the fact that lignite is almost exclusively used in the Austrian gas-works, the tar being consequently very poor in benzol. The Austrian printed calicos, especially those of Franz Leitenberger, of Cosmanos, deserve commendation, as also the turkey reds. There is a fine display of gauze

printed with woollen dust; the designs are printed upon the goods in starch-paste mixed with gum, and the dust of coloured wool applied, which adheres only to the moist parts; rich and novel effects are produced by this style, which is much admired for ball costumes.

The editor gives also receipts for black and brown on plush; for a salmon on wool and woollen yarns; for a light scarlet on the same materials, remarkable for the total absence of oxalic acid, the wares being, to 100 lbs. of wool—3 lbs. of tin crystals, 3 lbs. of tin-composition (perchloride), 3 lbs. of tartar, and $\frac{3}{4}$ lb. of cochineal. Further is a medium blue-green on woollen cloth, and three receipts for printing greens on calico.

No. 34, 1873.

An extract of sumac is now in great request. It is prepared by exhausting the ware with water, and careful concentration in a steam-bath, generally with the aid of the vacuum-pan. It is sold as a thick syrup, of a pure astringent taste, without the slightest acidity. This permanence is ascribed to the high concentration which appears to hinder the transformation into gallic acid.

In the French department we find a splendid assortment of anilin colours. Noteworthy is a corallin, said to be able to bear clearing (*avigage*) at a boiling temperature. The dye extracts of Coëz, and the natural alizarin and purpurin, orcin and orcein, of Meissonier also deserve mention.

The instructions for dyeing and finishing plush are continued. There is a receipt for Bordeaux—i.e., cherry-brown on wool, and a porcelain-white on the same material.

The announcement appears of an international exhibition of textile manufactures, to take place in Berlin.

For a black on cotton-wool, the goods are to be boiled for three hours in logwood liquor (30 lbs. to 100 lbs. of cotton); worked in a cold bath of 15 lbs. of chromate of potash and 10 lbs. of blue vitriol for an hour; put back into the old extract bath, cooled down to 60° R. (= 167° F.), in which 10 lbs. of soda-ash have been dissolved; worked for two hours, and saddened with 10 lbs. of copperas. A Dr. Kielmeyer recommends the use of acetate of iron, made by the direct action of crude pyroligneous acid upon scrap-iron (general in this country), in preference to the kind made by double decomposition of copperas and sugar-of-lead. He points out the (well-known) value of the tarry impurities in preventing peroxidation of the iron. He explains the addition of arsenious acid to black-liquor as calculated to exert a similar action. He concludes with the strange statement that acetate of iron at 20° Baumé is chiefly used in woollen dye-works for dyeing a black, the tarry matters co-operating as a black-dyeing ingredient!

Annalen der Chemie und Pharmacie, band clxviii., heft 2 and 3 (Neue Reihe, band xcii., heft 2 and 3), August 30, 1873.

On Ethyl- and Diethyl-Allylamin.—Albert Rinne.—The author finds that diethyl-allylamin is isomeric with the ethyl-piperidin of Cahours, its boiling-point being 25° lower.

Examination of the Isomeric Cresols, with reference to their Occurrence in Coal-Tar.—M. S. Southworth.—The author has examined meta-, ortho-, and para-cresol.

Sorbic Acid.—E. Kachel and R. Fittig.—(Second treatise).—An examination of sorbic tetrabromide, with its sodium, potassium, calcium, and zinc salts; the decomposition of the above salts by the action of heat; their behaviour with hydrogen; sorbic dibromide or dibrom-hydrosorbic acid and hydrosorbic acid.

Processes in the Interior of the Non-Luminous Flame of the Bunsen Burner.—R. Blochman.—A lengthy and exhaustive paper, illustrated with three plates, and occupying more than sixty closely-printed pages.

MISCELLANEOUS.

Public Analysts.—Mr. Wentworth L. Scott has lately been appointed Public Analyst, under the Adulteration of Food Act, for Derbyshire and Stafford, by the Justices for these counties respectively. Mr. Charles H. Piesse has been elected to the office of Public Analyst for the Strand district.

Metropolitan Gas.—Dr. Letheby, the chief gas-examiner appointed by the Board of Trade, has recently reported to the Corporation of London and the Metropolitan Board of Works of the quality of the gas supplied by certain of the Gas Companies during the last three months, and from this it appears that the average illuminating power of the common gas has been as follows:—Chartered Gas: at Beckton, 17.46 standard sperm candles; at Cannon Street, 16.58 candles; at Friendly Place, Mile End, 17.29 candles. Imperial Gas: at Carlyle Square, 17.51 candles; at Camden Street, 16.78 candles; at Graham Road, 16.51 candles. South Metropolitan Gas: at Hill Street, Peckham, 17.15 candles. The canal gas of the Chartered Company has averaged 21.54 candles at Millbank, and 21.16 candles at Ladbroke Grove. These results show that the illuminating power of the gas has been fully equal to the requirements of the Acts of Parliament. With respect to impurity, Dr. Letheby reports that the gas at all the testing-places has contained less ammonia than is prescribed by the referees, viz., 2.5 grains per 100 cubic feet of gas. The Chartered gas has been constantly free from sulphuretted hydrogen, but that of the Imperial Company and South Metropolitan Company has at times been charged with sulphuretted hydrogen, arising from accidental causes, created by the new regulations concerning the proportion of sulphur permitted to be present in the gas. The average amounts of this impurity has been as follows:—Chartered Gas: at Beckton, 12.44 grains per 100 cubic feet; at Cannon Street, in the City, 12.02 grains; at Friendly Place, Mile End, 13.77 grains; at Millbank, Westminster, 19.27 grains; at Ladbroke Grove, Notting Hill, 17.78 grains. The Imperial Gas: at Carlyle Square, Chelsea, 18.09 grains; at Camden Street, Camden Town, 12.27 grains; at Graham Road, Dalston, 17.60 grains. And the South Metropolitan Gas, 22.87 grains. Dr. Letheby remarks that the proportion of sulphur in the South Metropolitan gas compared with that in the Chartered gas indicates a want of skill in the conduct of the operations, which no doubt will be improved.

NOTES AND QUERIES.

Dyeing Black Kid.—Could any of your readers inform me how kid is dyed black, or where I might be able to get the information?—SUBSCRIBER.

Detection of Petroleum Spirit in Coal Naphtha.—Will any of our readers kindly inform me of a reliable method for the detection of petroleum spirit when present in coal naphtha? It being often used as an adulterant also, how can I distinguish between crude Scotch and English naphthas?—E. J. D.

Separation of Iron from Nickel and Cobalt.—Fresenius, in his "Quantitative Analysis," gives, for the separation of iron from nickel and cobalt and strong bases, a method which depends upon adding a solution of ammonia carbonate to the solution until the solution has lost its transparency. Will you kindly inform me, through the medium of your valuable paper, whether the carbonate used in this method is a solution of the ordinary solid carbonate, or a solution of the solid made neutral by ammonia?—A BEGINNER.

Notes on the Utilisation of Sewage.—(From the "Report of the Main Drainage Committee for 1864," vol. 487).

1313. (To Sir Charles Fox.) That would be 132,727,272 tons per annum would it not?—Yes.

(Mr. Smith.) The sewage proper will take 4,702 horse-power to lift it 180 feet, that is, allowing for friction; and for dealing with the gross sewage it will take 19,096 horse-power.

(Sir Charles Fox.) That is, Watt's horse-power of 33,000 lbs. lifted.

1321. (Sir Charles Fox.) We have taken 180 feet as the average height to which the whole sewage of London will have to be lifted; that is, of course, too much for some cases, and too little for others, but on an average we think it will meet the whole case.

1407. (To Mr. Smith.) You propose to construct, as filters, from 500 to 1000 acres of osier beds through which you will pass the sewage after it has left the other lands, in order fully to deprive it of all deleterious and injurious matters; are you uncertain as to the size of these osier beds?—The London Waterworks allow 2 square yards for a gallon of water per minute, and I think we have more than 10 square yards per minute.

1409. (Sir Charles Fox.) The water that is used for the purposes of irrigation and fertilisation must in a great measure find its way back again into the river; but our object is, to rid it of all its fertilising properties, and after it has been applied to the land to make use of it again in the growth of osiers; that is a very profitable operation, and it will take the last fertilising properties out of the water.

1410. (To Mr. Smith.) Has the osier any peculiar property of deodorising the water?—We always find osiers precipitating to a great depth in search of water, and, if you have a sewer or a drain, it is almost certain to be filled with roots of willows or osiers.

1411. (To the same.) Then it is not peculiarly valuable as a deodorant?—Its peculiar value is that it grows in water; the alder would be equally as good as the osier.

(Sir Charles Fox.) The osier is of unusually rapid growth, and consequently requires more fertilisation.

1416. (To Mr. Smith.) In frost the sewage does not sink into the land, does it?—I think it will. The temperature of the sewage, according to Mr. Mechi, is quite high enough to thaw a hard frost sufficiently to soften it.

(Sir Charles Fox.) I thought that the sewage would find its way back to the Thames, but Mr. Mechi thinks not, and Mr. Smith agrees with him.

1442. (To Sir Charles Fox.) Then would not the fertilising matter of the sewage be in great dilution?—In ordinary storm-water, the fertilising quality of the water is rather greater than under ordinary circumstances, from the fact of the water washing out the deposit from the bottom of the sewers. It so happens that the first portion of the storm-water washes out the greater portion of accumulation in the sewers, and that would pass away on to the lands, and it would only be the latter portions of the storm-water, which are very free from injurious matter, which would go into the River Thames, and that only during some of the summer storms.

1529. (To Mr. Smith.) Could you supply the farmers by measure through the pipes?—Yes, certainly, or by meter.

1530. (To the same.) Do you propose to do it through a gauge?—Yes.

1531. (To Sir Charles Fox.) Would not the gauge stop the flow of the sediment to a considerable extent?—No, there are plenty of water-meters that would let any sewage pass through without the slightest difficulty; in fact, perhaps one of the best is simply a screw beautifully hung, which the fluid turns round in passing through, and regulates the quantity with considerable nicety by the number of its revolutions, which are registered.

1816. (Mr. Ellis.) At page 36 of the First Report of the Select Committee on the Sewage of Towns, at question 776, Professor Way is asked "You have made experiments on the power of soils to absorb the manure contained in sewage?—Yes. Will you inform the Committee what were the results obtained by you?—The results generally were these:—That in soils there resides a power, which, previously to my examinations, I believe was not recognised, to separate from liquids containing manure—containing ammonia, for instance, and potash, and phosphoric acid, and magnesia, that is to say, all the important elements of manure, these elements; to separate them from water, not by mere filtration, because these things would pass through a filter, but by the peculiar chemical attraction possessed by the ingredients of a fertile soil for these liquids, so that if we were passing a liquid containing manurial matters through a given quantity of soil, the water would pass through, and these matters would be retained and fixed in the soil. I look upon this as a great arrangement and provision of Nature for the preservation of manuring principles from being washed out of the soil by rains."

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

An improved mode of reducing metals from their ores, and purifying and refining the same. Richard Werdermann, civil engineer, Princes Street, Surrey. February 10, 1873.—No. 424. My said invention relates to an improved mode of applying electric currents in order to reduce metals directly from the ores with or without the ordinary chemical action of carbonaceous matter, and in purifying and refining at the same time and by the same process the metal during its reception from the ore.

An improved mode of and apparatus for purifying and refining metals and alloys. Richard Werdermann, civil engineer, Princes Street, Surrey. February 10, 1873.—No. 426. My said invention consists in an improved mode of applying electric currents to remove the noxious elements mixed or combined with the metal or alloy, and to permit such noxious elements when required to be collected and purified; it also consists in improved apparatus whereby the currents are effectually employed.

A new or improved composition or paint to be used for coating metal and other substances. Walter Chiddock Nangle, Bull Point, near Devonport, Devon. February 11, 1873.—No. 495. This composition or paint is composed of coal-tar, rosin, plaster of paris, dry red-lead, spanish brown, and beasolin. The rosin is first dissolved by heat, then mixed with the plaster of paris; to these are added some tar, red-lead, and spanish brown, and when well mixed the remainder of the tar and other ingredients are added, and the whole boiled. When cold, the benzolin is added. This paint is particularly recommended for pre-

serving iron, but may also be applied with advantage as a coating for other metals and substances.

Improvements in the manufacture of chlorine. Henry Deacon, alkali manufacturer, Appleton House, Widnes, Lancashire. February 11, 1873.—No. 505. This invention relates to improvements upon Deacon's chlorine process, and consists in mixing the active substance or substances employed with one or more substances of another class, which when used alone are inactive or inert, that is, do not possess the power of decomposing heated hydrochloric acid gas and air or oxygen in any material degree, but when mixed with the sulphate of copper, *cateris paribus*, materially increase its activity in this respect. Sulphate of soda and sulphate of potash are types of this class of inactive but, so to say, accelerating substances.

Improvements in the manufacture of corks, and in the apparatus employed therein. Jules Salleron, cork manufacturer, 24, Rue Pavée, Paris. February 11, 1873.—No. 509. The invention consists—First, in testing the cork by submitting it to a pressure of 6 to 7 atmospheres in presence of pure or alcoholised water, in which cork of bad quality becomes spotted and black; the soft parts of the corks hollow out, and the cork itself assumes an oval form, and loses its form if the cork is of bad quality. Secondly, in forming the corks of pieces of thin cork of good quality grouped together so that the front of the bark shall form the circumference of the cork, and the hard veins in supporting each other form a cork of equal elasticity throughout its diameter and very strong; and in attaching these pieces together by means of a solution of dry india-rubber before being pressed together, partly in cementing a disc of cork for the head of the cork. Thirdly, in forming the corks of two pieces of cork back to back with a cement of india-rubber so as to leave the front outside. Fourthly, in covering the corks of an inferior quality with a sheet cut from cork of good quality parallel to the hard layers of the back.

An improved process to be employed in the manufacture of manures, and machinery or apparatus therefor. Samuel William Maquay, Charlemont Terrace, Dublin. February 12, 1873.—No. 511. This invention consists in manufacturing manures from coprolites or similar substances by the continuous application and employment of acid and other gases within closed vessels in connection with endless elevators and revolving stirrers.

Improvements in the manufacture of manure and apparatus therefor. Hugh Campbell, physician, 38, Queen Anne Street, Cavendish Square, Middlesex. February 12, 1873.—No. 513. To saturate absorbent and nitrogenous substances with solutions and liquids containing ammoniacal salts, ammonia, or its chemical elements, and afterwards to reduce the combinations so obtained to powder, so as to facilitate their rapid, cheap, and easy distribution over land.

Improvements in obtaining oxygen. Charles Weightman Harrison, High Holborn, Middlesex. February 12, 1873.—No. 528. This specification describes obtaining oxygen from atmospheric air by passing the air into suitable porous substances or by precipitating the oxygen of the air by magnetic or electro-magnetic action.

The manufacture of a new composition for the removal and prevention of incrustation in steam-boilers. Charles Burdett, civil engineer, Surrey House, New Wimbledon, Surrey. February 13, 1873.—No. 538. The above composition not only effects the removal of old deposits, and prevents any fresh incrustation from forming, but effectually preserves the iron, and at the same time is free from any ingredients that are injurious to the cocks, valves, or other portions of the machinery. The composition is manufactured in three forms for the convenience of users. The *block* form can be applied to stationary boilers through the man-hole. The *liquid* form can be applied to stationary or locomotive boilers through feedwater cistern, or through safety-valve by shutting off the steam. The *paste* form contains ingredients almost identical with the liquid, and is in fact a highly condensed form of the liquid. It is manufactured for the especial purpose of saving space and expense in transit. On being liquidised in warm water it can be applied to boilers in same manner as the liquid form.

Improvements in the manufacture of sulphurated lead, in apparatus therefor, and in its application to various useful purposes. James Noad, engineer, of Bower Road, Hackney Wick, in the county of Middlesex. February 13, 1873.—No. 539. My invention relates to the manufacture of a compound of sulphur and lead, which possesses very peculiar properties, and is applicable to many useful purposes. I use two pots placed over separate fires, and connected by pipes with a mixing chamber. The latter is to be provided with an inlet pipe for air or steam, and an outlet pipe leading to a condenser. It also has a rake or rabble. I melt lead in one of the aforesaid pots, and sulphur in the other; when the lead is heated to about 710° F., and the sulphur to its melting-point, I open the communications, allow the liquids, in the proportion of 5 parts lead and 1 part sulphur, to flow into the mixing chamber. The lead has by this treatment been converted into a dark grey brittle powder. The said powder, after being ground, sifted, bolted, or floated, and dried, will be ready for use for various purposes.

TO CORRESPONDENTS.

R. Brown.—Nearly neutralise with carbonate of soda, and precipitate the gold in the metallic form with proto-sulphate of iron.

R. Kiley.—(1). Write to Trübner and Co., foreign booksellers, Ludgate Hill, for the American journals; they are published weekly. (2). About the end of the present year.

BOOKS RECEIVED.

The Worthies of Cumberland. By Henry Lonsdale, M.D. G. Routledge and Sons.

An Easy Introduction to Chemistry. Edited by the Rev. Arthur Rigg, M.A. London, Oxford, and Cambridge: Rivingtons and Co.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE**, **AGRICULTURE**, and **COMMERCE**.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES under the direction of Professor E. V. GARDNER, F.E.S., &c. of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W

Royal Polytechnic Institution, 309, Regent

Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with **PATENTS** conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for **GOVERNMENT EXAMINATIONS**.

Classes are now forming for Practical Study in **CHEMISTRY**, **STEAM**, and **PHYSICS**.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A. at the Institution.

Analysis of Food, Water, and Air.—Mr.

WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

MR. C. ESTCOURT, F.C.S.,

ANALYTICAL AND CONSULTING CHEMIST.

Commercial Analyses of all kinds performed.

BOROUGH LABORATORY,

8, St. James's Square, John Dalton Street, MANCHESTER.

THE LIVERPOOL COLLEGE OF

CHEMISTRY, 96, DUKE STREET, LIVERPOOL.

Specialty Devoted to the Study of **CHEMISTRY, TECHNOLOGY** and **ASSAYING**.

Laboratories open throughout the Year.

MARTIN MURPHY, F.C.S., &c., Principal (Successor to the late Dr. SHERIDAN MUSPRATT).

A Special Laboratory is devoted to Commercial Analyses of every description, and to Mineral Assays.

Manufacturers' and Smelters' Analyses and Assays undertaken on Contract.

Patentees and Inventors Advised and Assisted. Works and Mines Inspected. The Erection of Manufacturers' Plant Supervised, &c.

Terms and Fees VERY MODERATE.

Further Particulars and Full Prospectus on application to The Principal, **MARTIN MURPHY, F.C.S. &c.**

Two Courses of Lectures on Geological

MINERALOGY will be given at **KING'S COLLEGE, LONDON**, by Professor **TENNANT**, to which the public are admitted on paying the College fees. One Course is given on Wednesday and Friday mornings, from 9 to 10 o'clock, commencing Wednesday, October 8th, and terminating at Easter, 1874. The other Course is given on Thursday evenings, from 8 to 9, commencing October 9th. The Lectures are illustrated by a very extensive collection of specimens.

Practical Instruction in Mineralogy and Geology is given by Prof. **TENNANT, F.G.S.**, at his residence, 149, Strand, W.C.

ROYAL POLYTECHNIC.—Notice.—THE

ENCHANTED GLEN (written by Dr. Croft), notwithstanding its great popularity, cannot be given after November 8, in consequence of the engagement of Mr. Howard Paul. This week 300th representation; Mr. Hartwell. New Lectures by Professor Gardner:—1. "The Silber Light;" 2. "Sugar, from the Cane to the Teacup;" "Home Electricity," Mr. King. Other Novelties.—Open daily, 12 to 5 and 7 to 10. Admission, 1s.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 727.

PUBLIC ANALYSTS.

A NUMBER of important chemical appointments have been created by recent legislation, and it is matter of notoriety that some of these appointments are filled by persons only very imperfectly qualified to discharge the duties devolving upon them. We allude to the public analysts, and invite our readers to inspect the official list of these appointments. It is indeed doubtful whether there exist in this country a sufficient number of duly qualified persons to fill all these offices; and we observe, accordingly, a very portentous development of pluralism—one gentleman and his assistant (or coadjutor) having been actually appointed public analyst for no fewer than *seventeen counties*. As we have said, there is a dearth of competent analysts, and to some extent pluralism is excusable. We can, however, hardly avoid thinking that the exigencies of the case do not warrant the entrusting of so many of these appointments to the same hands, and we hope that, on the expiration of the official year, these gentlemen will be relieved of a portion of the burden and responsibility which has been laid on their shoulders. Passing from the office holders to the work which they have accomplished, we have to note an unpleasantly large number of errors, and a growing distrust of the official analyst.

Liverpool and Glasgow have, each of them, had their butter-scandal, and even the milk-analysis of a public analyst has been called in question. In London there have been alum-convictions of the most doubtful character, and, at the present moment, there is a tea-controversy in Birmingham.

It was indeed inevitable that, on the first establishment of the office of public analyst, there should be a good deal of blundering on the part of the officer; and it is perhaps matter of congratulation that the early blunders have been so very patent and instructive. A fact which might otherwise have been ignored has been made very apparent, namely, that the ordinary laboratory course which a chemical student passes through in this country, is totally inadequate to prepare him for the discharge of the new duties, and that special instruction is imperatively demanded. It has curiously enough happened that the most notorious and picturesque failures, on the part of the public analyst, have been instances where the analyst had enjoyed the advantage of the ordinary analytical course, and where he probably presumed on the adequacy of such a training.

If we had been asked to say beforehand how it would be, we should have been disposed to point to the medical man, with a smattering of chemistry, who had taken office on the strength of the smattering, and should have looked for striking blunders from that quarter. And no doubt, too, there will be cases of wonderful failure of this description. The danger from this source is indeed so real as to need no special illustration; and it is well that the early working of the new regulations has proved an illustration of dangers which were by no means obvious.

THE POLLUTION OF RIVERS' BILL.

(SECOND ARTICLE.)

BEFORE proceeding further with our examination of this Bill, and of the evidence laid before the Committee of the Lords, we cannot help quoting a portion of Sir W. Fergusson's address delivered at the meeting of the British Medical Association, just to remind our readers that the chemical point of view is not the only one from which the water question may be regarded:—"Supposing that the greatest chemist in the world places a pint of pure water, absolutely without alloy, at the meal of his fellow man, let us, as medical men, do what the community at large cannot, trace this fluid until it is no longer palpable. Take as a type the pet of the day, the 'working man,' allow him to be a model teetotaler who has taken a vow against alcohol and all fermented liquors. He takes his frugal meal—say water and bread. Trace that meal as far as your physiological imagination can, down the intestinal canal, and into the blood, and fancy, from your knowledge, the affluents thereon. Can 'pure water' be recognised beyond the teeth in this downward course? Mucus, saliva, tonsillary secretion, mucus again and gastric juice, and pancreatic and biliary, all join the ingredients of that simple meal. But let us suppose the working man indulges in the luxury of a bit of beef or mutton, with some of the usual adjuncts; what is the fate of the pint of pure water, which is deemed the grand feature of this excellent fare? Here vegetable and animal matter are joined with pure water to an extent a thousand times beyond the imagination of the pure water theorist. Look even at the condition or risk of the epicure, whose means permit him to indulge in the high-flavoured grouse or daintily managed venison, and suppose him a 'pure water' man, what becomes of the water as soon as swallowed? What about the pleasing adjuncts to these delicious articles of food, and what (to those who are always referring to salts in water) about the common salt which is consumed in quantities palpably larger than those pointed out by the chemist in so-called saline waters?"

Do we, therefore, disapprove of the movement for improving, wherever and however practicable, the condition of our streams? No more than does Sir W. Fergusson himself. But we do most earnestly protest against this movement being made subservient to the vanity and the ambition of any man, or being employed for the consecration of unwise crotchets.

To return to the Rivers' Bill. Dr. Frankland, in his evidence, brings forward the names of a number of scientific men of very various degrees of eminence, who, as he asserts, pronounce his "standards perfectly practicable, and recommend them strongly." Hearsay evidence is not generally considered very reliable. We should like to hear these chemists examined as to their alleged approval of these "recommendations," and called upon to state their reasons for deeming them practicable, judicious, or expedient. We fear that, before such an examination had proceeded very far, Dr. Frankland's admirers would be very much reduced in number. No authority can justify such an assortment of errors and omissions.

The following passage is worthy of public attention:—

"Lord Aveland: Does that sewage farm (Merthyr Tydfil) pay? Dr. Frankland: I should think not. If you were to debit against that farm the cost of draining the land, and the cost of bringing the sewage to it, it certainly would not pay. Even an irrigation farm where you spread the sewage over an enormously larger area of land does not always pay."

Dr. Frankland also believes that if an act which compelled the purification of water—we presume on "recommendation" principles—were put in force, it "would greatly benefit nearly every manufacturer in the country individually."

The gentlemen who gave evidence on behalf of the various manufacturing interests concerned expressed a

very natural doubt as to the practicability of the scheme proposed. It is interesting to observe how their scruples were met. The case of the Alkali Act was duly paraded before the vision of the public. In that instance manufacturers were ordered by the law to do something which had not been customary, and which was generally deemed impracticable, to condense, namely, 95 per cent at least of the hydrochloric acid gas generated in their establishments. They succeeded in doing much more than the law demanded, and that not without benefit to themselves. But it is questionable logic to assume that, because one such piece of audacity proved so splendidly successful, a similar fortune will always await enactments of this kind. Who have been louder than the Rivers' Pollution Commissioners in expressing their conviction of the impossibility of dealing with town sewage by chemical means? Yet the liquid refuse of manufacturers is no less complex, no less dilute. Since their "recommendations" were put forward, moreover, the price of fuel has greatly risen, and an additional difficulty has thus been placed in the way of the remunerative treatment of such refuse.

But space does not allow us to linger any longer over clause 6 and its shortcomings. Other gems await our notice. Clause 15 informs us that, if pollution is proved against any person, judgment shall be given against him, "notwithstanding that it may appear that the particular pollution complained of is not separately appreciable, by reason of the existence of some other pollution in the neighbourhood." This clause gives facilities for a process of unnatural selection. Small offenders may thus be seized upon, while greater ones escape. This clause, besides, establishes the principle that a man may pollute a river, and incur penalties, by pouring into it water cleaner than the river in question.

Clause 16 speaks of repeated acts which may be held together to cause a pollution, though each act, taken by itself, may not be sufficient for that purpose. This clause is full of doubt, and therefore of danger. Are we to understand that liquids coming within the recommendation standards may yet, under certain circumstances not named, be held polluting?

Worse still is clause 21. This Act is not to be the sole and all-sufficient method of dealing with the pollution of rivers, but it is to be "in addition to" any powers which existed before. This is simply to create and foster complexity and confusion. Fix your standards high or low, but let the manufacturer know that, when these are fairly obeyed, he is safe. If the Bill is not to be all-sufficient, clause 6 notwithstanding, why pass it? Is not this very 21st clause a confession of worthlessness?

But the end crowns the work. We read with admiration that this Act "shall not affect any outfall or other works of the Metropolitan Board of Works (though beyond the Metropolis), or take away, abridge, or prejudicially affect any right, power, authority, jurisdiction, or privilege of the Metropolitan Board of Works." In other words, the greatest offender is to go scot-free! The corporations of Liverpool, of Manchester, of Birmingham, of Bristol, of Leeds, will find their privileges most disagreeably affected if they presume to pollute their respective streams and rivers. But what is sauce for the goose is not sauce for the gander. Crossness and Barking are still to be left free to pour pollution by millions of gallons daily into Father Thames. This looks very like an attempt to buy off the opposition of the Metropolitan members. But what will be the result upon the provincial cities and towns. If it does not stimulate them to the fiercest opposition they must be more—or less—than human.

One more point must not be overlooked. The Bill, stipulating for the exclusion of waters containing "organic nitrogen" beyond certain specified proportions, says nothing of the manner in which the amount of such organic nitrogen is to be ascertained. The public have a right to demand a guarantee that the process employed shall not be a well-known one, which is almost universally acknowledged to give erroneous results. Manu-

facturers must not be mulcted in severe penalties according to the results of a fallacious procedure. It is very possible that this Bill, as it stands, may not become law. Unless the "recommendations" are expunged or fundamentally modified, unless it is made a Bill for testing rivers as well as their inlets, and unless the clauses for making it practically null and void are cancelled, it must be our duty to warn both the authorities of provincial towns and all manufacturing chemists to oppose it at every stage of its career. That we need a good Act on the subject is no apology for passing a bad one. The Rivers' Pollution Commission, we are told, expires at the end of this year. It will serve to moderate our regret if its works follow it.

THE IRON ORE OF THE BIDASOA, AND ITS TREATMENT BY CALCINING AND LIXIVIATION.

By Dr. ERNST RÖHRIG, M.E., and ROBERT HAAS.

THE iron mines of the English Mining Company in Iron are situated on that part of the Pyrenees which runs alongside of the river Bidasoa, in the Spanish provinces Guipuzcoa and Navarre.

The ores occurring in these mines are less known than those of the province of Bilbao, which are of great renown, chiefly on account of the large deposit of good iron ore at Somorastro.

The ores of the Bidasoa have been worked on a large scale only a few years; this short time has, however, been sufficient to prove the vast extension of the ore and its excellent quality. The ore is particularly fit for the production of Bessemer pig, as it contains no phosphorus, and on the other hand it contains an amount of manganese.

The proximity and easy access to the Bidasoa from all mines of the Company allows a cheap transport of the ore to the railway station at Hendaye; besides which a railway for conveying the ore is in course of construction, so as to afford the means for transporting any quantity of ore from the mines to the various places of embarkation.

Thus the gain by selling the ore is not inconsiderable; it could, however, be increased three- or four-fold if the ore were converted into pig in the neighbourhood of the mines. The ores occur in lodes of steep inclination, and of an average width of 4 or 5 metres.

The lodes are chiefly found in a formation which here occurs in masses, and is termed by Charpentier granite formation. As, however, the mineral contains no mica, and essentially consists of quartz, orthoclase, and hornblende, its proper termination would be syenite. Other lodes of iron are found in siluric rocks adjoining the syenite, and also in limestone belonging to the trias formation.

The ore itself consists almost exclusively of spathic ore, which is usually transformed into brown iron ore in the parts nearest to the surface. The quality of the ore may be judged from the following lists of analyses:—

I. ORES FROM SAN CARLOS MINES.

(a). Spathic Carbonate of Iron.

Iron	34.27	42.08	39.99	36.75
Manganese ..	1.82	2.54	3.99	6.05
Sulphur	0.09	0.06	0.03	0.04
Silica	—	9.80	5.48	6.87

(b). Brown Iron Ore.

Iron	48.53	51.02	49.83	26.16	16.67
Manganese ..	3.39	3.84	4.87	13.29	43.13
Sulphur	—	0.04	0.03	—	—
Silica	—	9.49	9.44	—	—

II. ORES FROM THE "ALBION" MINES.

(a). Spathic Carbonate of Iron.

Iron	41'23	40'05	38'75	40'20
Manganese ..	2'77	3'77	3'72	4'00
Sulphur	0'15	0'27	1'39	0'64
Silica	7'88	3'44	—	—

(b). Brown Iron Ore.

Iron	54'63	52'25	52'64	54'20	47'66	52'70
Manganese ..	0'25	0'40	0'45	0'78	1'84	4'44
Sulphur	0'04	0'03	0'07	0'08	1'36	0'99
Silica	9'36	12'70	14'30	—	12'32	—

III. ORES FROM THE "THREE CROWNS" MINES.

	Brown Iron Ore.	Spathic Ore.	Brown Ore.
Iron	55'61	56'47	41'67
Manganese ..	0'38	0'90	3'70
Sulphur	0'16	0'06	0'05
Silica	4'09	4'05	3'02

IV. ORES FROM THE "SAN BENITO" MINES.

Spathic Ore.

Iron	36'88	39'52
Manganese ..	2'71	2'86
Sulphur	0'06	0'06
Silica	20'53	13'65

The excellent quality of the ore is further proved by the fact that these ores have been worked for many centuries in Catalan forges with good success, and in many places they are still worked.

The above analyses show also that some of the ores contain a considerable amount of sulphur, and although these sulphurous ores form but a comparatively small portion of the whole, trials for removing the sulphur, by means of a suitable calcination and lixiviation, have been made by us. These trials were carried out most successfully. By means of an oxidising calcination we obtained satisfactory results, shown by the following analyses:—

Spathic Ore of San Miguel.

	Raw Ore.	Calcined Ore.
Iron	42'19	54'43
Sulphur	0'54	0'16

Spathic of San Benito.

Iron	36'07	50'34
Sulphur	0'34	0'18

The amount of sulphur remaining in the calcined ore is so small as to allow of a direct smelting of the ore in blast-furnaces, with an addition of limestone, which will remove the last trace of sulphur. Still better results were obtained by treating ores containing a large amount of sulphur, although the calcining oven at disposal was of imperfect construction, having been used formerly for burning lime, and had to be re-constructed for our purposes as far as circumstances would allow.

In order to find out the limit to which sulphur may be removed by a suitable calcination and methodic lixiviation, we have artificially mixed ore, so as to contain 2½ per cent of sulphur. The results obtained by the treatment of this highly sulphurated ore are shown by the accompanying analyses. (See next column).

The lixiviation of the ore has been considered as finished when a sample of water taken from the apparatus for lixiviation, after being acidified with hydrochloric acid, did not give any more reaction with chloride of baryta.

The small quantity of sulphuric acid, i.e., 0'15 per cent, corresponding to 0'06 per cent of sulphur, as shown by analysis III., proves that the lixiviation had not been carried on long enough in the apparatus. We have removed it by a subsequent boiling of the ore in the state of powder, when it was shown that 0'07 per cent of sulphur could not be removed, and remained in the ore. The

* Ins. = in insoluble combination; s. = soluble combination.

† As it was not possible to determine the state of oxidation of the Mn, we have taken it for granted that the Mn is transformed, by the calcining process, into Mn₂O₄.

‡ The total amount of sulphuric acid formed out of FeS₂ after half of the sulphur has been evaporated.

same result would have been obtained undoubtedly by a further lixiviation in the apparatus. The remaining sulphur, 0'07 per cent, consists of FeS, and is taken as such in calculation in analyses II. and III.

To control the latter analyses, we have made calculations contained in the two columns (b), by which we also proved that calcination, as well as lixiviation, has been perfectly rational. Our calculations are founded on the supposition that, under the process of calcination, all the water and carbonic acid are evaporated, while the oxidisable components of the ore take a higher state of oxidation; thus FeO and MnO will form Fe₂O₃ and Mn₂O₄, and FeS₂, losing 1 equivalent S, is transformed into Fe₂O₃ and SO₃.

The small differences found by comparing the columns (a) and (b) are chiefly founded in the inevitable differences which always arise in taking samples at different times from the same heap, and it may be possible that some mechanical loss of ore has taken place in the process of lixiviation. The analysis II. is composed of two analyses, containing the soluble part and insoluble part of the ore. 100 grms. of the calcined ore has been boiled until all the soluble parts were extracted; their composition is the following:—

MnO ..	0'36
Al ₂ O ₃ ..	0'10
CaO ..	0'56
MgO ..	0'15
SO ₃ ..	1'70
	2'87

Total, 2'87 grms. of sulphates, contained in 100 grms. of calcined ore, and if calculated for 100, the following lixiviated salts appear:—

Al ₂ O ₃ SO ₃ ..	11'50
MnO SO ₃ ..	25'78
CaO SO ₃ ..	47'39
MgO SO ₃ ..	15'33
	100'00

or very nearly a salt composed of 1 equiv. Al, 5 equivs. Mn, 10 equivs. Ca, and 4 equivs. Mg, if calculated on the foundation of their equivalent weights. The amount of

insoluble components (*vide* Table, "ins.") was found by deducting the soluble components from the total analysis of the calcined ore.

It was not possible to ascertain the total quantity of soluble salts and their weight in a direct way, as part of the salts loses its composing water at a lower temperature, and as the sulphates of alumina and manganese are decomposed at a higher temperature. However, we ascertained that sulphate of lime first separated, when boiling the lixiviated salts to dryness.

The lixiviation had a weak, sour reaction, as sulphate of alumina has this property even as a neutral salt.

The determination of sulphur was made in all the three analyses with especial care. We applied the dry way (with soda and saltpetre), and also the wet way (with hydrochloric acid and chlorate of potash), and our figures represent the average of various analyses. Chloride of iron was removed from the solution before adding the chloride of baryta, which was done to the solution in a boiling state; the solution was kept boiling for half an hour, and kept for twelve hours more at a temperature of about 40° before the precipitation of baryta was filtrated.

The analysis of the soluble salts proves the interesting fact that no iron whatever has entered into solution, as is generally supposed, although in the present case sulphuric acid, in sufficient quantity for the formation of vitriol of iron were at disposal.

The same fact took place in the calcination of other kinds of manganiferous ores; in all cases, not a trace of iron could be ascertained. The presence of manganese, together with that of Ca, Al, and Mg, seems to prevent the formation of sulphate of iron, in case these bases be present in sufficient quantity to neutralise the SO_3 that has been formed.

The most favourable result of having reduced, by the calcining and lixiviating processes, the original amount of sulphur in the raw ore of 2.53 to 0.75 per cent and 0.07 per cent respectively, we think must be attributed to the presence of Mn and Ca in the ore; and the behaviour of manganiferous ores of the Bidasoa during roasting makes it probable that manganese acts, in the calcining process, for the removal of sulphur, in a similar manner as it is known to act in the various iron and steel smelting processes.

We intend to make comparing trials with ores rich in sulphur and free from manganese at the same time.

Irwin, Sept. 1, 1873.

SEWAGE AND THE UTILISATION OF ALUM SHALE.

By SIDNEY W. RICH.

THAT the purification and utilisation of sewage is still a problem requiring solution is known to most persons; it is, however, not so well known that unnumbered tons of a material which is well suited to break the back of the difficulty now lie waste—I speak of the alum shale cropping up at Whitby, Guisborough, and in other parts of England and of Scotland. This shale has long been used for the manufacture of alum and epsom salts, but the process employed being a crude, wasteful process, the works have one by one broken down, being unable to bear the competition with more modern works and more modern processes developed at Manchester, Newcastle, Goole, and elsewhere. Nevertheless, this shale is peculiarly adapted to the manufacture of alumina salts, and, consequently, is likely to render material assistance at all events towards a partial solution of the sewage difficulty.

The final opinions of the British Association Committee on the Utilisation and Purification of Sewage embraced the statement that, "by properly conducted sewage irrigation, a solution is afforded to the question of sewage utilisation," while, at the same time, "a precipitation process, or some clarifying process, may be found useful."

Few people will deny that some clarifying process should be applied to the sewage before it is run on to the land; indeed, it is probable that, if effluent water alone were used for irrigation, choking of the land would be less likely to occur, and, consequently, the land would take more sewage and cause less annoyance. Fewer people still will deny that, if the sewage is to be run into a river, it is still more necessary to employ an efficacious precipitation process, in order that the effluent water may be as free as possible from obvious impurity. In either case a cheap precipitating agent is required, and there can be no doubt that in some form of soluble alumina only can we find such an agent. Practically, if the effluent water is to be used for irrigation purposes, a very small quantity of alumina will sufficiently clarify the sewage; on the other hand, if the effluent water is to flow directly into a river, a large quantity must be used. To test the results afforded by these different degrees of clarification, I have experimented on a very large scale at the Tottenham Sewage Works, and I find that, by reducing the amount of soluble alumina to the lowest figure compatible with the production of a clear effluent water, a deposit may be easily obtained, containing, when dry, 3 per cent of ammonia. I obtained, however, a different result when I aimed at getting an effluent water as pure as possible—the quantity of precipitating material being increased, the ammonia in the deposit was proportionately decreased. I would therefore clarify the sewage more or less perfectly according to its immediate destination; if irrigation is in view, a double profit may be expected—that on the application of the effluent water and that on the deposit. If, on the other hand, perfect artificial clarification is aimed at, regardless of the expense, the loss must be borne. With respect to the deposit, a great difficulty arises—it is by no means saleable. This must, however, be got over by special means in each locality. In dealing with the London sewage, and, wherever any large sandy area is available, it cannot be better applied than to the stiffening of the sand. Containing, as this deposit does, a large proportion of alumina, it is precisely the most suitable material that could be applied to sand. It should be partially dried, and then ploughed in, and the work, if in its first stages a loss, should be considered a national work of reclamation. A sandy tract, stiffened with this aluminous deposit, irrigated with effluent sewage water, and cropped with rye-grass, must, in the course of time, develop into a highly fertile area.

Many schemes are before the public, advocating the use of alumina in one form or another, commencing with potash-alum and ending with raw clay. The proper selection of the specific material may be advanced by a consideration of the requirements. The alumina should be in the soluble condition, and must be in a fit condition for transportation perhaps many miles; it must be comparatively cheap. These considerations alone will show to any reasonable creature the folly of using alum, and even sulphate of alumina at its present price. In a less degree, the unsuitability of clay, whether in combination with sulphuric acid or not, is evident. Sulphuric acid, as such, is far too expensive to be cast away by the ton, while clay becomes impossible immediately the question of transport arises. Where transport is necessary, a concentrated material must be used, and clay can never furnish this. And yet consideration will show that a combination of sulphuric acid and alumina—in other words, that some form of sulphate of alumina—is the only material which meets all our requirements; it contains a suitable proportion of soluble alumina, and is therefore portable, but at present it is dear. It is dear because its manufacture involves the use of sulphuric acid, which is, alone, an expensive manufactured article. These considerations forced themselves on my mind eighteen months since, and I trust I shall not be accused of the endeavour to push a pet theory if I give an account of my subsequent action in the matter. Convinced of the necessity to

manufacture sulphate of alumina without the use of sulphuric acid, I set to work and experimented on the aluminous shale at Guisborough. As a result of my experiments I found that at a suitable temperature the burnt shale combined with sulphurous acid gas, provided air and moisture were present, sulphate of alumina being formed. To carry this out practically, I built a brick cell 18 feet high, and caused the shale immediately as it burnt, and while still hot, to sink into the cell. By withdrawing the burnt material from the bottom, and continually renewing the heap of burning shale at the top of the cell, I was able to keep up a continuous passing of material down the cell. I now caused the introduction of sulphurous acid gas at the bottom of the cell from a pyrites-burner; air and moisture were introduced at the mouth of the cell. Owing to the high temperature within, and to the joint presence of the several agents, the whole of the sulphurous acid gas was converted into sulphuric acid, and, in consequence, masses of the burnt shale came down in large part converted into soluble sulphate of alumina. This invention forms the subject of a patent, whilst an improved method of lixiviating the crude sulphate of alumina forms the subject of another patent. The method of lixiviation employed involves the treatment of the hot crude sulphate with water, in tubs which run on an inclined tram, and work on the principle of the lixiviating vats for alkali. The crude sulphate being lixiviated immediately it is removed from the cell, and while it is at a high temperature, the liquor becomes boiling hot, and may be drawn off at a highly concentrated point; indeed, very little expense is involved in the matter of fuel and evaporating-pans. The net result is that sulphate of alumina may now be profitably manufactured on the large scale for 25s. or 30s. a ton.

In the event of a cheap sulphate of alumina being utilised for sewage purposes, I would recommend the value of the article to be determined by the percentage units of soluble matter precipitable by ammonia, irrespective of its precise character, *i.e.*, of the proportion of soluble silica, precipitable lime and magnesia salts, &c., provided there were no more than some specified maximum of oxide of iron present.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 201).

LECTURE V.

On the Energy of Electricity, with Especial Reference to the Measurement and Utilisation of it.

THE energy of electricity is being manifested in phases new to men day by day. That which in the early part of the present century was unknown is now so well known as to win neither surprise nor notice. The telegraph which girdles the earth—the electro-deposition of metals—the light which pales our brightest—the power which melts the most refractory metals (for I have seen a square bar of iron a foot in length, and about three-eighths of an inch on the side, fused into drops by a current of electricity in less time than this narrative has occupied)—these have been handed down by science to promote the commercial and social welfare of mankind.

What remains to be done by this energy, so recently harnessed, and as yet only partially trained, is beyond our present ken; but that it will—or, at least, that it can—be developed in a sufficiency to supply our coal-fields when exhausted, and take upon itself all that coal, and wind, and water now give of kinetic energy, no one who has watched the progress of the past need doubt; this, too,

quite irrespective of the view that owing to the quantity of zinc consumed electricity can never compete with coal in producing the same results. There is every reason to expect that long ere the coal-fields are exhausted the tidal waves on our coasts will be supplying light enough and heat enough, and, therefore, power enough, for the requirements of Great Britain and Ireland.

Propositions better established than that which asserts electricity to be non-producible from sufficiently economical sources have faded into oblivion.

The energies of electricity are manifested whenever there is a molecular disturbance within or amongst bodies. Whenever any change takes place in anything whatever, and amongst any molecules whatever, an electric current is produced, and if not necessarily manifested to us, still it always is present. Probably there is not a single act of our lives, and it may be not even a thought in our heads, which is not associated with an electric current.

Kindly understand that the lecture is on the energy of electricity, and, therefore, time must not be occupied in describing instruments. Galvanometers are now-a-days made so delicate that if you lay one finger in one trough of salt water, and another in another, and simply tighten the muscles of one arm, a current of electricity passes through the galvanometer and deflects the needle. We cannot raise our hands to our head without setting free a current of electricity, and in that current is energy. Its energy is manifested in the moving of the galvanometer needle. How much of that energy is merely the balance between two energies of large amount—how much is not manifested, owing to the sluggishness of the instrument and from other defects, we know not, but that some is thus interfered with there is very little doubt. We usually speak of a galvanic battery as being formed of zinc and copper, or of metals in chemically different relations to a liquid; if, however, you take a piece of ordinary copper bell-wire, and connect the two ends of it to the galvanometer, then cut it in two with a pair of scissors, and dip each cut end into salt and water, or put them into your mouth, an electric current passes, and the galvanometer shows that there has been some species or other of molecular disturbance which has caused a manifestation of electrical energy.

This energy of electricity becomes kinetic when it is allowed to pass freely. For example, in any bodies which are quiescent, it is kinetic, but it is potential when resisted. If, for instance, a current of electricity passes along a wire and the action is resisted, the wire becomes hot. If it passes through any compound body, as, for instance, water, then it is resisted, and the water is immediately decomposed. Consequently we are dealing to-night with an energy manifested in molecular disturbance, and having both a potential or stored-up power, and a kinetic power in motion. The question now is, how is this energy to be measured? for the subject of the lecture this evening is a mode of measuring the energy of electricity.

Towards the middle of the last century (about 1746) the first electrical machine was made. In 1650, Otto Guericke, to whom we are indebted for the air-pump, suggested the scheme, but Hawksbee was the first to make one. His machine consisted of a ball of sulphur, afterwards altered to a ball of glass. The hands were employed to rub it, and a large fly-wheel, about 6 feet high, was employed to turn it. Silk threads from the ceiling held what we now call the conductor; and by the exercise of a very large amount of mechanical power they were enabled to get a small spark, to the surprise of all, to the curiosity of many, and the dread of not a few. After that we come to the plate machine, which is arranged, as you are aware, with cushions; still we have those sparks which were supposed to have much energy in them. We then pass on from the glass plate machine to the vulcanite plate machine. Here is a vulcanite plate, and, as you are aware, by rotating it between cushions, the electricity is gathered upon this conductor. You see this large wooden ring—that was suggested by Winter

* The Cantor Lectures, delivered before the Society of Arts.

the object of it was, somehow or other, we do not know how, to condense the electricity, and to convert what might be a fine line spark into a solid whitish spark. How this ring acts, and the whole history of this machine, would be quite sufficient matter for one lecture; but that with which we are now concerned is not how to produce such phenomena, but how to attempt to measure the energy of the electricity which these machines, and other means, can develop. I scarcely need tell you that it is not, in any sense of the word, an electrical lecture in which we are to be engaged this evening, and these apparatus are only here as illustrations of the operations. Sparks pass from the conductor, and are usually charged into a jar of this kind—a Leyden jar. That was first done in the year 1746. The jars were charged and discharged, and although great shocks were felt, yet no measure was taken, and it was supposed that in the shock consisted the energy of electricity.

Now, the mode in which electricity thus presenting itself was ultimately measured was by a small jar of this kind, called a unit jar. This unit jar is in all respects the counterpart of the Leyden jar, only made smaller, and one is here mounted on glass and brass rods. There are two brass balls, one connected with the inside of the jar and one with the outside, which balls can be set at any distance apart. The inside of the jar is charged from the electrical machine, and as soon as it is sufficiently charged, according to the distance of the balls from one another, a spark passes. So passing, spark after spark enters the larger jar, and if we count the number of such entering we have settled what was supposed to be the measure of energy contained in the large jar. We may put in 10, 20, 30, or 40 charges. It will be very obvious to you, however, that these unit jars vary. The same jar is always alike, but you cannot make two exactly alike. Even if this could be done, the state of the atmosphere and other surroundings would so influence the passing electricity that accurate comparisons and conclusions could not be made. Moreover, these jars vary on the surface, and in the character of the glass, and in other ways; consequently this mode of measuring energy must necessarily be a failure. The unit jar, therefore, has fallen into complete disuse.

Hitherto the mode of producing the electricity to be measured has been by friction. Now, here is a machine, consisting of a thin circular vulcanite disc, capable of being put in rapid rotation, but there are no rubbers or other articles in contact with the plate. It is called a Bertsch machine. Here are three segments of thin vulcanite; one of these is rubbed with a piece of dry silk or fur, and, being slid in prepared grooves, the faces of the segment and rotating vulcanite are about one-quarter of an inch apart. These two other segmental pieces can be slid behind the first one; if the room and the atmosphere were not so damp we should probably get a 4-inch spark from this machine. One segment is rubbed, and placed about a quarter of an inch from the disc, and by a process of induction, when it is rotated, there is a noise as of much electricity being brought forward and gathered by the conductor. Again, we have here no quantity of electricity—we have no kinetic energy. The difference between energy as it is used, speaking electrically, and intensity, as it is also used, speaking electrically, is this, there may be great intensity and little or no quantity—no power, in the proper sense of the word. For example, if a piece of iron were taken and formed into needles, and if those needles were placed points downward upon the hand, and a small weight upon them, we should find that piece of iron was possessed of great intensity; but if this iron in rough block form, with any weight upon it, be placed upon the hand, although there be a very much larger quantity of iron, yet there is little intensity. In such a sense the distinction is drawn in electricity between quantity and intensity. There is great penetrative power in electricity obtained from this machine; but there is no quantity of

electricity moving, and upon the quantity in motion depends our ability to get energy. If all our iron appeared in the form of needle-points we should do very little with it.

There is another matter, also peculiar to electricity of this character, compared with the uses to which iron is now applied. Here is a small glass flask with crumpled pieces of tin-foil in it. If this flask were coated on the outside, as a jar is, the amount of intensity and the shock that would be given by it, would be equal to what might be obtained from that large jar, for this reason, the electrical balances between the inner superficial metal surface and the outer coating of the jar depend upon the intensity on these two. Electricity of this character rests upon surfaces only; electricity of that other character, with which we are more concerned, enters below the surface, and may be said to reside and travel within the body. Whatever, therefore, may be the number of, say, square inches of surface within the jar, the electricity upon the whole of them would be balanced by electricity of equal intensity upon an outer surface covering the jar only. This may be illustrated by a reference to the large quantity of water contained in a dock for ships. It is supported or kept at its level by a gate which in no respect is stronger than would be required for a dock of the same depth containing not one-tenth of the quantity of water. So with what is called the hydrostatic paradox, also so with Bramah's hydraulic press, and so with this little jar. There may be a large quantity of electricity within this jar if it have a large surface on which to distribute itself, and then it will be balanced or kept in equilibrium by a smaller surface on the outside charged to the same intensity.

The electricity here has been produced through physical exertion. We found, however, the other night that there is no physical exertion so great as that which takes place between the molecules of different bodies when chemical affinity is allowed to operate. If, therefore, instead of getting molecular disturbance in the muscles of our arms by turning these handles, we produce molecular disturbance between the ultimate atoms, or molecules of matter, forces are called into play as far beyond the power of our arms as those of the most colossal steam-engine are beyond the power of a mouse. By chemical arrangements we are enabled to obtain electricity of a totally different character from that hitherto noticed—so different that there is little similarity between them, excepting a common name. In fact, the earlier attempts at telegraphy failed in consequence of the promoters using electricity produced by machinery such as this—an electricity which is possessed only of intensity, and not of that energy consequent upon quantity.

(To be continued.)

OBITUARY.

CRACE-CALVERT.

WE record with deep regret the death of Dr. F. Crace-Calvert, whose contributions to chemistry have so frequently enriched our pages. Crace-Calvert spent the early years of his life in France. After his return to England he became Honorary Professor of Chemistry in the Royal Institution of Manchester, which position he continued to hold up to the time of his death. In 1850 he was also Lecturer on Chemistry in the Pine Street Medical School, Manchester, an appointment which he does not seem to have held later than 1855. In 1859 he was elected a Fellow of the Royal Society. He was also a Corresponding Member of the Academy of Sciences of Turin, Honorary Member of the Pharmaceutical Society of Paris, and Corresponding Member of the Industrial Society of Mulhouse. He died on the 24th inst., at the age of 54. For many years we enjoyed the pleasure of his friendship, and few can give more able testimony to his worth as a chemist or his faithfulness as a friend.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 29, 1873.

New Researches on the Analysis and Theory of the Pulse in the Normal and Abnormal States.—(Continued.)—M. Bouilland.—The author here treats of lesions relative to the number and force of arterial beats, the rhythm of beats and repose of arteries and of the heart, the absence or temporary suspension of beats of arteries and of the heart, and the supposed abnormal diastole of the pulse. [M. Bouley, in a note following this one, points out that it is no new view that the arteries contribute, by their elasticity, to the circulating movement of the blood; having been held by John Hunter, Magendie, Dr. Blainville, and others: but M. Bouilland explains in reply that it is a certain systole or pulse of the arteries, rhythmic like the ventricular systole that he considers new.]

Observations on Subjects Treated in No. 21 of the Memoirs by an Officer of Engineers.—Gen. Morin.—Some facts as to the effects of German fire on the forts of Paris are cited from the work, which appears to be of some value in military engineering.

Note on Magnetism.—(Continued.)—M. Gauguin.—In a permanent magnet the curve representing currents of detachment (*d'arrachement*) sinks very rapidly from the extremities to the heel, where it coincides with the axis. In an electro-magnet the curve is nearly a straight line in the interval between the two bobbins, parallel with the axis of abscissæ, and high above it. The increase of magnetisation from application of the armature is, in the latter, nearly uniform throughout the length of the bar; in the former it is much greater at the extremities than at the heel. The current of demagnetisation, produced on rupture of the inducing current when the electro-magnet is without armature, varies nearly as the intensity of the latter for a given point in the magnet. On the other hand, the current of detachment is about proportional to the square of the inducing current. Hence the relation of the current of detachment to the current of rupture itself varies as the intensity of the inducing current. In a series of experiments cited, the proportion of the two currents of demagnetisation was 62·8 with a weak inducing current, but it may be raised to 100. Again, the increase of magnetism in a permanent magnet from application of the armature is independent of the duration of contact. In the case of an electro-magnet, the reaction from application of the armature is effected in a very short time, but it is not instantaneous. The magnetic state was (under the conditions of experiment) appreciably modified during four or five seconds. M. Gauguin further experimented as to the apparently neutral state of magnets pointed out by M. Jamin; first, sending through the bobbins of an electro-magnet, having armature attached, a current of the intensity 17,980 (measured by a conical multiplier); then, after a few seconds circulation of this, a current of contrary direction and intensity, 8900, for a few seconds. After these operations the iron core does not possess any apparent magnetism, but it has the property of being magnetised more energetically in one direction than the other, when subjected to two equal inducing currents of contrary signs and of less intensity than 17,980. The magnetisation in any case was very slight, but could be

measured by the method of currents of detachment. Conformably to M. Jamin's observations the author found the inequality of the two magnetisms effaced as the current approached the intensity of 17,980. The apparently neutral state can be obtained a great many different ways, the iron having different properties in each case. The author supposes a superposition of alternate layers of contrary magnetism, positive and negative. He experimented by sending through the bobbins of an electro-magnet with armature—1, a current considered positive, of intensity 17,900; 2, a negative current, of intensity 11,100; 3, a positive current 5898. After this process the iron has no sensible magnetism, but it has the following properties:—When an inducing current of determinate strength is passed alternately in opposite directions the two magnetisations, positive and negative, are generally unequal, and their relation varies with the intensity of the inducing current. When this intensity is little above 5898, the negative magnetisation is considerably above the positive; with intensity 8606 the two magnetisations are equal; as the intensity continues growing the positive intensity becomes superior; it is much the greater for intensity 11,100; and, lastly, the two magnetisations become equal again for intensity 17,900. To explain these effects it must be supposed that the bar contains two layers of positive magnetism, separated by one of negative.

Zeitschrift für Analytische Chemie, Zwölfter Jahrgang, Erster Heft, 1873.

Determination of Phosphoric Acid in Baker-Guano and Similar Raw Materials (Malden, Jarvis, Enderberry, Starbuck, and Howland-Guano).—Dr. C. Gilbert.—A condition necessary for the correct determination of phosphoric acid in those methods where it is finally precipitated with magnesia-mixture, or estimated by means of a uranic solution, either gravimetrically or volumetrically, is that the acid should be present in the tribasic state. In the materials above mentioned the acid is in the tribasic state, but not always saturated with lime, sometimes magnesia and basic water replacing more or less of the lime. In many cargoes of these guanos lumps occur of nearly pure so-called neutral phosphate of lime—

sometimes in union with gypsum. Phosphoric acid is generally determined in a hydrochloric or nitric solution of the incinerated, and more or less strongly ignited sample. The half-phosphate of lime on ignition passes into pyrophosphate, which on solution in acids, and even on long digestion at a moderate heat, is not completely re-converted into orthophosphate. This error is most serious in volumetric determinations with uranic solution, and least in cases where the phosphoric acid has been separated with the molybdic mixture; since the prolonged digestion in the nitric-molybdic solution re-converts a large proportion of the pyrophosphoric acid into orthophosphoric. Bunsen's method, on Reynoso's principle, excludes this error, as it requires evaporation in strong, preferably fuming, nitric acid. Fresenius recommends, in his instructions for the determination of phosphoric acid in guano, to fuse the sample with carbonate of soda and nitre, thus at once oxidising all organic matter, and ensuring the solution of all phosphoric acid in the tribasic state. But this advice is neglected in practice. Stohmann even recommends, in his treatise on the commercial examination of manures, to dissolve the ash of guano direct in nitric acid, and to employ this solution in the determination of the phosphoric acid. The author recommends the following procedure:—2·5 grms. of the sample, dried if the manure is in a very moist condition, mixed with four times its weight of a finely-powdered mixture of 2 parts of dry carbonate of soda and 1 part chlorate of potash, which should be kept ready. The

mixing is performed with a glass rod fused round at the end, in a capacious platinum crucible. The dust adhering to the rod is wiped off with a bit of Swedish filter-paper, and added to the mixture in the crucible. The flame applied is small, and is not brought very near, and under these conditions the ignition proceeds quietly without loss. As soon as the contents of the crucible are white the heat is increased, and the material is kept in flux for a quarter of an hour at full redness. When cold the crucible is placed in a beaker covered with about 150 c.c. of water, covered with a watch-glass, and about 30 c.c. of nitric acid, of specific gravity 1.25, are poured down the side into the beaker. The mass dissolves if no clay or sand is present easily and regularly. If silicic acid is present it is removed in the usual manner. The solution is then made up to 500 c.c., and used for the determination of phosphoric acid. The uranium volumetric method he modifies as follows:—100 c.c. are put in a beaker for a preliminary trial. The liquid is rendered faintly alkaline with pure soda-lye, and then made acid again with a little acetic acid. This procedure is preferable to adding acetate of soda. The solution can be at once titrated, as the raw materials in question rarely leave a distinct precipitate of phosphate of iron or alumina undissolved. Solution of acetate of uranium is then allowed to drop into the cold solution. The solution of ferrocyanide of potassium is to be prepared fresh daily, or the dry salt applied in powder. In gravimetric determinations of phosphoric acid the author recommends that the magnesia mixture be made without sulphate, which if present is partially deposited along with the double phosphate. The proportions are:—For 1 litre, 101.5 grms. crystalline chloride of magnesium ($\text{MgCl} + 6\text{HO}$), 200 grms. chloride of ammonium, and 400 grms. ammonia of sp. gr. 0.96. In the analysis of materials like ground bones, animal charcoal, and gelatinous bodies, the chloride of potash in the fusion mixture is replaced with saltpetre. The Baker guano contains 45.93 per cent phosphoric acid; the Jarvis, 36.71 per cent; the Enderberry 44.11 per cent; and the Starbuck, 35.54 per cent. In an appendix Professors Fresenius and Märcker and Dr. Ulex express their approval of Dr. Gilbert's procedure.

Experience in Chemical Jurisprudence.—Heinrich Struve.—A paper on the detection of hydrocyanic acid in poisoning cases.

Detection of Grape Sugar along with Dextrin and Analogous Bodies.—C. Barford.—The author's object was to find a method of readily and certainly detecting small quantities of sugar in presence of a large amount of dextrin. A solution of acetate of oxide of copper, containing a small quantity of free acetic acid. 1 part of crystalline neutral acetate of copper is dissolved in 15 parts of water, and 200 c.c. of this solution are mixed with 5 c.c. of acetic acid, containing 38 per cent of anhydrous acid. A few drops only of the test-liquid are added to the solution in question, the mixture is boiled only for a moment, and if the reaction does not ensue forthwith it is allowed to stand for not more than a couple of hours. If set aside for a longer period without examination the precipitate formed may be re-dissolved. The same test-liquid serves for the detection of grape sugar, not merely along with gum and cane sugar, but also when associated with milk sugar. All these three bodies behave like dextrin. Solutions of milk sugar must not be too concentrated or suboxide of copper may be separated on boiling.

Method of Determining Sulphur of General Applicability.—A. Sauer.—This process is adapted for determining the sulphur in coal and coke. The sample is burnt in a stream of oxygen, and the sulphurous acid formed is collected, hydrochloric acid containing bromine. A full description of the process would be unintelligible without the accompanying figures.

Precipitation of Magnesia.—Dr. Mohr.—Magnesia is generally precipitated after lime from an ammoniacal

solution which has been kept clear by means of sal-ammoniac by phosphate of soda. The precipitate, gelatinous at first, passes on standing into the crystalline double phosphate of magnesia and ammonia. If the liquid is filtered too soon, a further precipitate is formed in the filtrate, and it is necessary to filter again. The case is quite different when, instead of phosphate of soda, a solution of double phosphate of ammonia and soda is employed. A crystalline precipitate appears at once, and in a few moments it is completely deposited.

Contributions to the Qualitative Analysis of Vine Leaves.—C. Neubauer.—The author detected tartar, tartrate of lime, quercetin, quercitrin, tannin, starch, tannic and malic acids, gum, inosit, sugar, oxalic acid, a crystalline body soluble in ether, ammonia, phosphate of lime, and gypsum.

Comparative Determinations of Alcohol.—Dr. A. Kraft.—A lengthy paper on the different methods of determining alcohol in wines.

Prevention of Explosions During the Use of Apparatus for Generating Hydrogen Gas.—Dr. R. Fresenius.

Technological Chemical Gas Analysis.—H. Fresenius.—Both these papers would be unintelligible without the accompanying illustrations.

Volumetric Determination of Zinc.—O. Schott.—In the sulphide of sodium process the author recommends glazed card-paper (containing carbonate of lead) as an indicator.

Detection of Chlorine, Iodine, and Bromine in Organic Matter.—C. Neubauer.—A little oxide of copper is introduced into the loop of a platinum wire, and heated till it adheres. It is then dipped into the substance, or a little of the latter if dry is sprinkled upon it. The loop is then brought into the flame of a gas-burner moderately opened, near the lower and inner margin of the flame. The carbon burns first, and the flame becomes luminous followed by the characteristic blue or green colour.

Detection of Alcohol in Essential Oils.—R. Böttger.

Analysis of Cheese.—Alexander Müller.—This paper is unsuitable for abstraction.

Test for the Fastness of Turkey Red.—Armand Mueller.—Equal weights of the samples of dyed cloth or yarn are placed in equal measures of the following mixture:—10 vols. of alcohol at 96 per cent Tr., and 1 vol. hydrochloric acid at 1.18 sp. gr. Large quantities of the solution are used, and the whole is gently heated on the water-bath to about 50° C. The time is noted when each swatch become discharged. It appears that the greater the amount of alumina in a Turkey red the longer it resists the extracting mixture. The author concludes that the oil is only then serviceable when it has completely passed into that unknown, generally called oxidised, state in which it ceases to be soluble in ether.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 250, October, 1873.

Report on Bloch's Feculometer (Farinometer).—Presented by M. Cloëz.—Pöato starch, which is now used in constantly increasing quantities in the manufacture of dextrin and of glucose, is found in various states of hydration, in which the water ranges from 16 to 50 per cent. The intermediate stages are very difficult to identify by their appearance or touch. Bloch's instrument serves to determine the amount of water present in a manner sufficiently accurate for commercial purposes. It consists of a glass tube formed of two parts of different diameters; the lower, 0.220 metre long and 0.016 metre in diameter, is closed at one of its ends; it serves to contain the starch and indicate its value, for which purpose it carries a graduated scale. The upper part fused on to the lower tube serves for a funnel. It is a cylinder 0.180 metre long and 0.028 metre in width, and is closed

above with a glass stopper. To graduate his instrument Bloch has set out with the principle that pure starch, not modified by heat or the action of acids, if in presence of an excess of water combines with a certain quantity of that liquid, forming, according to the author, a hydrate of known volume. After having exactly determined by drying the quantity of moisture contained in a sample of starch, if we take a quantity of such starch supposed to contain 10 grms. of dry farina, and place it in a graduated tube in contact with common spring water or river water, we find after a certain time that it occupies the volume of 17.567 c.c. This is the starting-point for the graduation and the construction of the farinometer. The lower tube should have a capacity of about 20 c.c. 17.567 c.c. are carefully measured into this tube, and the volume occupied by this is then divided into 100 parts of equal capacity. It is evident that each degree represents 1 per cent of dry farina. To make the assay an average sample of the starch is taken, and 10 grms. are weighed and introduced into the tube with common water. It is well shaken so as to beat up and mix the solid matter; then a slender stream of water is allowed to flow along the inside of the upper tube so as to rinse down all adhering particles of the starch. The apparatus is then set aside for an hour or two until the starch is deposited, and does not move if the apparatus is inclined on one side. The number of degrees on the scale occupied by the starch is then read off. This number represents the proportion in hundredths of real starch; if this, e.g., is 76, 100 kilos. of the sample contain 76 kilos. of starch, and 24 kilos. of water of hydration. This is the limit of composition of a commercial starch which does not roll into balls in the hand.

Report on Marine Glue, and on an Impermeable Liquid Glue.—M. Barral.—An account of the uses of two kinds of marine glue manufactured by Madame Audouin. The impermeable liquid glue serves to make troughs of paste-board for photographic purposes, capable of resisting the action of nitrate of silver, and even highly concentrated nitric acid.

Bulletin de la Societe Chimique de Paris, tome xx., Nos. 4 and 5, September 20, 1873.

Use of the Hydrosulphite of Soda for the Titration of Oxygen and Oxidised Compounds, and on Certain Novel Facts Concerning Oxygen.—P. Schützenberger and Ch. Risler.—This important paper, which requires an illustration, will be given entire at an early opportunity.

New Experiments on the Respiration of Fishes.—Dr. Quinquand.—A physiological paper. The determinations of oxygen have been made by the method of Schützenberger and Risler.

Process for Determining the Hæmoglobin in the Blood.—Dr. Quinquand.—An application of the same method.

Researches on Indium.—M. C. Roessler.—The specific heat of indium requires its equivalents to be 113.4, and leads us to ascribe to its oxide the formula In_2O_3 . Hitherto this view has been unsupported by facts, but the author has succeeded in obtaining the alum of indium and ammonium, $\text{In}_2(\text{SO}_4)_3 \cdot \text{NH}_4\text{SO}_4 + 24\text{H}_2\text{O}$. This alum is very soluble, water at 16° C. dissolving twice its weight, and at 30° four times. The solution on boiling deposits a white powder. The salt is insoluble in alcohol.

Constitution of Certain New Uraniferous Minerals.—Cl. Winkler.—The following minerals have been found in the Weisser Hirsh mine at Schneeberg, and have been examined by Weissbach:—*Uranospherite*.—Hemispheric brick-red masses which decrepitate on heating, and are resolved into a number of silky needles,—

Walpurgine, a basic arseniate of bismuth and uranium (Bi_2O_3), $\text{As}_2\text{O}_5 + (\text{U}_2\text{O}_3)_3 \cdot \text{As}_2\text{O}_5 + 10\text{H}_2\text{O}$. On calcination this mineral turns brown, and after cooling appears of a

deep orange-yellow, without alteration in the form of the crystals. *Tragerite* (arsenate of uranium)—

forms yellow crystals, which lose water when heated, and become temporarily of a golden-brown without modification of form. Their yellow colour returns on cooling. *Zeunerite* (arsenate of uranium and copper),—

This mineral forms fine green crystals resembling chalcocite, or phosphate of uranium and copper. Chalcocite from Redruth contains 3 per cent of arsenic acid, whilst zeunerite is free from phosphoric acid. *Uranospinite*, $(\text{AsO}_4)_2 \cdot \text{Ca}(\text{UO})_4 + 8\text{H}_2\text{O}$, is of a pale yellowish green and corresponds to uranite. If nitrate of uranium is added to a solution of oxide of copper in arsenic acid there appears a turbidity, and green crystalline lamellæ are formed, or, if the solution is hot, a crystalline powder agreeing in composition with zeunerite.

Detection of Tellurium and Sulphur in Ores.—G. Kustel.—To detect tellurium in ores which contain it in the state of telluride of gold the author uses sodium amalgam. The powdered ore is placed in a capsule with a little water and mercury, and afterwards a little sodium amalgam. If tellurium is present the water takes a violet colour. If it contains sulphur the water blackens silver-foil. If sulphide of iron is present the violet colour produced by the telluride of sodium may be masked by the precipitate occasioned. In such cases the water is poured off, a fresh quantity of water added, and the test is re-commenced with a fragment of sodium amalgam.

Reaction of Tellurous Acid.—F. Stolba.—Tellurous acid, mixed with an excess of alkali is reduced by glucose; if the solutions are dilute, and a large quantity of glucose be employed, the whole of the tellurium is deposited as a black powder. Selenious acid is not reduced under the same circumstances.

Apparatus for the Analysis of Gaseous Mixtures.—

M. Orsat.—By means of an aspirator, which may be merely a bottle half-filled with water, and connected by a caoutchouc tube to a graduated jar which serves for measurement, and which may be raised or lowered by hand, we introduce into the jar 100 c.c. of gas. Then, by raising the aspirator, this gas is transferred into a first receiver which contains a solution of potassa at 40°; the carbonic acid is absorbed. The decrease of volume is noted. The gases are then transferred to a second receiver, ammoniacal hydrochlorate of ammonia and metallic copper, carbonic oxide and oxygen are absorbed, and a fresh decrease of volume is noted. What remains is nitrogen if the products of combustion are under examination. The volume of oxygen being known, if we deduct the quantity of oxygen which has been introduced along with it, and has served to form carbonic acid and carbonic oxide; then as oxygen is transformed into carbonic acid without change of volume, while it is doubled on becoming converted into carbonic oxide, the joint increase of volume of the oxygen, and the carbonic acid as compared with the initial volume of oxygen, represents half the volume of the carbonic oxide produced. Chlorine and sulphurous acid can be absorbed by means of suitable reagents.

Method of Printing Anilin Colours on Calico.—

(*Moniteur de la Teinture*).—A solution of gelatin is prepared containing about 50 grms. to the litre of water. Solution of bichromate is added drop by drop till a straw-colour is produced; the anilin colour is then added, and the mixture thickened with dextrin or with roasted starch. After printing the pieces are exposed for some hours to light, which renders gelatin insoluble in contact with chrome. The gelatin may be replaced by a solution of casein in a small quantity of ammonia.

Reimann's Färber Zeitung, No. 35, 1873.

The Vienna Exhibition.—The display of dyed silks from Lyons is particularly beautiful. A novel feature is

the display of the various dye-wares along with the dyed goods. The paper-hangings in the English department are pronounced unique and splendid.

Dyeing and Finishing Plushes.—The author continues this subject in considerable detail.

Use of Epsom Salts in Dyeing.—In dyeing wool for goods which require to pass under the stocks, it has been observed for some time that an addition of epsoms gives greater permanence to the anilin colours, especially primula and methyl-violet. An addition of sulphurous acid is also found advantageous for the same colours. The colours are brighter and less inclined to rub off.

Cochineal-Red on Cotton.—To 10 lbs. of goods take 10 ozs. of tannin, and dissolve it completely in boiling water. Lay the goods over-night in the solution. Prepare some red liquor at 12° Baumé, and put into a small tub a sufficient quantity to work 2 lbs. of cotton yarn. Work the yarn for ten minutes. Fill up the red liquor to its original quantity, and work 2 lbs. more; and so on, till the whole of the yarn has been mordanted; it is then allowed to dry, with frequent turning. Piece-goods are winced for an hour in red liquor of the same strength. When dry, the goods are passed through a boiling bath of 1 lb. of prepared chalk to every 10 lbs. of cotton, and washed twice. 1 to 1½ lb. of cochineal is boiled out in water; a colour-bath is made up at 40° Reaumur, with the addition of a little flavin, and the goods are worked, raising the temperature slowly to near the boiling-point.

There are receipts for a Nicholson blue, a cochineal ponceau, and a magenta ponceau on silk, the colours for the latter being hydrochlorate of rosanilin and hydrochlorate of chrysanilin. There are also receipts for a claret, a mouse, and a drab on wool.

New Reaction of Saffranin.—If a few granules of the colour are mixed with 2 drops of concentrated sulphuric acid on a porcelain capsule, and stirred, a splendid blue colour immediately appears. The addition of 2 drops of water converts the blue to an emerald-green, and, by continued alternating additions of acid and water almost all the prismatic shades can be produced with remarkable beauty.

Revolution in the Alkali Manufacture.—According to R. Wagner, Leblanc's process is about to be superseded in England, Austria, and Germany. A solution of chloride of sodium is converted by bicarbonate of ammonia into chloride of ammonium and bicarbonate of soda; the latter crystallises out, while the chloride of ammonium remains in solution. This chloride of ammonium is distilled with limestone, and yields carbonate of ammonia, which is converted into bicarbonate by the excessive acid of the soda salt. No sulphur or sulphuric acid is needed. The soda obtained is very strong, and free from sulphur compounds. Plant, fuel, and labour are economised, and the escape of noxious gases is at an end. (As soon as we see this system at work we will examine its probable consequences—scientific, sanitary, and commercial.

NOTICES OF BOOKS.

Ville de Bruxelles, Assainissement de la Senne. Utilisation des Eaux d'Egout de l'Agglomération Bruxelloise. Usines de Haeren, Irrigation des Plateaux Sablonneux de Loo et de Pexthy. Par LEON DEROTE et CHARLES VAN MIERLO. Bruxelles: Baertsoen et Cie.

WORKS on sewage and its utilisation are becoming almost as plentiful and as agreeable as sewage itself. The pamphlet before us does not attempt to throw any new light upon this vexed question of modern times. Its authors, two "engineers of bridges and highways," content themselves with the easier task of repeating the questionable, or more than questionable, statements which circulate in England, and allowing them to mislead their country-

men. Had they, like the Prussian commissioner, Lefeldt, come and seen with their own eyes, we must, in common charity, suppose that their reports and conclusions would have been very different. Amongst the grosser errors, we find a statement that MacDougall's process—disinfection with sulphite of magnesia and carbolate of lime—has proved a failure. The fact is that the Carlisle irrigation-plot, where the sewage undergoes a preliminary treatment with these materials before being admitted upon the land, is almost the only farm of the kind which has neither given rise to complaints of nuisances nor proved a nursery of parasites. Whether it has proved a commercial success we are unable to state, but if not it has merely shared the common lot of irrigation-farms. With reference to the sanitary effects of irrigation-farms on their vicinity, a very important piece of evidence has come to light in a "Blue-book" lately issued, entitled "Progress of India for the Years 1871 and 1872," drawn up by C. R. Markham, C.B. We find it here stated that as early as 1847 an epidemic which was then experienced in the north-western provinces was more general and more severe than elsewhere. A committee of investigation recommended that irrigation should not be brought within 200 yards of the villages, and that a double row of trees should be planted round as a barrier. Now it is very true that nuisances of all kinds are less formidable in Belgium or in England than under the sun of India; But, on the other hand, in India irrigation is conducted with clean water, and is only applied when the rain-fall is deficient. If under such circumstances it is pernicious, how much more will this be the case when the land is irrigated continuously, and with offensive water. If a sewage-farm requires to be encircled with an uninhabited district, the expenses of the system, formidable enough already, will be still further augmented. We trust that our Belgian friends will not suffer themselves to be misled. Let them procure M. Lefeldt's pamphlet, and contrast its revelations with the loose statements of Messrs. Derote and Van Mierlo, and they will hesitate before committing themselves to irrigation schemes. The charge against precipitation, that it was unable to purify sewage, has been so strikingly refuted that it is tacitly withdrawn. Even the last ground of its opponents, the alleged worthlessness of the deposit as manure, is giving way before the irresistible logic of facts. Perhaps such manures *ought* not to produce remunerative crops, but they do, in spite of our theories. We cannot help saying that if Messrs. Derote and Van Mierlo will in future leave chemical questions—such as the treatment of sewage—to chemists, it will be better both for their own reputation and for the public.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 3rd.—Royal Institution, 2. General Monthly Meeting.
THURSDAY, 6th.—Chemical, 8. H. Grimshaw and C. Schorlemmer, "On the C₂H₅NH₂ Acid and Normal Heptyl Alcohol." D. Howard, "On the Optical Properties of some Modifications of the Cinchona Alkaloids." J. B. Hannay, "On the Expansion of Carbon Disulphide, and the Action of Iodine Trichloride upon that Substance." W. F. Donkin, "On the Estimation of Nitrates in Potable Water."

Analysis of Food, Water, and Air.—Mr.

WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

Two Courses of Lectures on Geological

MINERALOGY will be given at KING'S COLLEGE, LONDON, by Professor TENNANT, to which the public are admitted on paying the College fees. One Course is given on Wednesday and Friday mornings, from 9 to 10 o'clock, commencing Wednesday, October 8th, and terminating at Easter, 1874. The other Course is given on Thursday evenings, from 8 to 9, commencing October 9th. The Lectures are illustrated by a very extensive collection of specimens.

Practical Instruction in Mineralogy and Geology is given by Prof. TENNANT, F.G.S., at his residence, 149, Strand, W.C.

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 727.

ESTIMATION OF SULPHUR IN IRON AND STEEL.

By T. J. MORRELL.

THE more common method of estimating sulphur in iron and steel consists in acting on the metal with sulphuric or hydrochloric acid, and precipitating some metallic sulphide by the evolved sulphuretted hydrogen. It would be a desideratum, in point of time, if this sulphide could be directly weighed.

By passing the evolved gases through an ammoniacal solution of cadmium oxide (or a solution of sulphate to which an excess of ammonia has been added), a precipitate of cadmium sulphide is obtained, which can be at once collected upon a small filter, dried at 212° F., and weighed.

The phosphoretted hydrogen, evolved in a solution of the metal together with the sulphuretted hydrogen, causes no precipitate in the solution.

The presence of ammoniacal salts would also prevent any precipitation of carbonate of cadmium by the traces of carbonic acid in the air drawn through the apparatus by the aspirator after the metal is dissolved. However, the aspirated air could easily be passed through potash solution, to remove its carbonic acid.

To prevent the precipitation of oxide of cadmium on the filter, the precipitate should be washed with distilled water containing diminishing quantities of ammonia.

If, in very accurate estimations, it is necessary to estimate the minute quantity of sulphur left in the solution and residue of the metal, this can be done as usual and added to that found as above.

Five test analyses of a piece of Bessemer steel known to contain 13 per cent of sulphur, gave as follows:—
(1) 0.124 per cent; (2) 0.125 per cent; (3) 0.137 per cent; (4) 0.125 per cent; (5) 0.124 per cent.—*American Chemist*.

Cambria Iron Works, Johnstown, Pa.

ON CHLORIDE OF MERCURETHYL.

By J. M. MAISCH.

THIS compound, it appears, has recently been introduced in Europe into medicine, and it is claimed for it that it may be used in the same doses and for the same purposes as corrosive sublimate, over which it has the advantage of not precipitating albumen, no matter in what solution the latter may be, whether as egg albumen, in the serum of blood, in urine, &c. Schering and Co. have introduced it under the name of *Hydargyrum athylochloratum*.

It was discovered by Strecker* and by Dünhaupt† in 1854. The former chemist started with iodide of ethyl, preparing therefrom as the first step the iodide of mercur-ethyl; the process of the latter involves the previous preparation of bismuth-triethyl, which being decomposed by corrosive sublimate, yields the compound in question, besides chloride of bismuth-ethyl. Whichever course is followed, the process, or rather series of processes, are

t tedious and complicated; but that of Strecker appears to offer better advantages in utilising all the material.

Iodide of ethyl or hydriodic ether= C_4H_5I , was discovered by Gay-Lussac in 1815, and prepared by distilling absolute alcohol with hydriodic acid, and separating the compound from the distillate by water. Serullas* subsequently improved the process by using iodine and phosphorus with alcohol, and Personnet found the use of amorphous (instead of ordinary) phosphorus very advantageous, using again absolute alcohol. The latter process was rendered more practical in 1862 by Reith and Beilstein,† who proposed to put 1 part of red phosphorus into 5 per cent of alcohol, sp. gr. 0.83, placing the flask with the mixture into cold water, adding 10 parts of iodine, distilling after twenty-four hours, shaking the distillate with soda solution, and removing the oily liquid which is rendered anhydrous and rectified. Lieben communicated, in 1868, to the Vienna Academy of Sciences, his observations that the chlorides of the alcohol radicals are converted into the iodides on being heated to about 130° C., with an excess of concentrated hydriodic acid. Wanklyn|| and De Vrij§ have simplified the preparation of iodide of ethyl very much by using absolute alcohol, to which a little more than one molecular weight of iodide of potassium is added, after which dry hydrochloric acid gas is passed into the liquid; or the hydrochloric acid is first passed into the alcohol and sufficient iodide of potassium added afterwards; after twenty-four hours the mixture is distilled, the iodide of ethyl separated by water and purified by washing, drying, and rectifying.

Iodide of ethyl is a colourless oily liquid of 1.93 sp. gr. at 15° C. (60° F.), of a strong and peculiar odour, and boiling at about 70° C. (158° F.). When digested with mercury or some other metals, ethyl compounds of the metals are obtained. In this manner and by taking advantage of the influence of diffused light, Strecker prepares the iodide of mercurethyl, re-crystallising the product from alcoholic ether. It forms then colourless iridescent scales, subliming at the temperature of boiling water, fusing at a higher temperature, of an unpleasant odour, and being decomposed by direct sunlight finally into mercuric iodide; its composition is C_4H_5HgI . If its alcoholic solution is precipitated by nitrate of silver and the filtrate carefully evaporated, crystals or a crystalline mass of nitrate of mercurethyl are obtained, which is readily soluble in water and almost as freely in alcohol.

This nitrate is easily converted into the chloride by adding to the aqueous solution of the former, muriatic acid or chloride of sodium, nitric acid, or, in the latter case, nitrate of sodium being separated in the aqueous solution.

Chloride of mercurethyl has the composition of C_4H_5HgCl : it forms white thin scales with an almost silvery lustre, and of a peculiar ethereal unpleasant odour; it is very sparingly soluble in cold water, little in ether and cold alcohol, but freely in boiling alcohol, crystallising again on cooling; it sublimes at 40° C. (122° F.) without fusing previously, and condenses in thin laminæ; exposed to the air it evaporates completely, and heated in a water-bath it may be fused to a clear oily liquid, which evaporates without leaving any residue. When rapidly heated upon platinum foil it burns with a slight flame, the vapours having a disagreeable odour and a metallic taste. Being very poisonous, it must be handled with great care on account of its ready volatility. Schering regards it as pure if it is readily and completely volatilised, dissolves without residue in boiling alcohol, yields in alcoholic solution but a faint reaction of chlorine, and, with alkali, does not produce a precipitate.

It remains to be seen whether its inactivity upon albumen renders this new claimant for medical favour so

much superior to corrosive sublimate and similar mercurials, that its good qualities would more than outweigh the dangers and uncertainties that must result from its ready volatility at our usual summer temperature.—*Am. Journ. Pharm.*

ATOMS.

DR. C. R. A. WRIGHT, commenting on some remarks made in an article in the *Athenæum*, writes as follows to that paper:—

In that article you have done me the honour of singling me out (not in the most tasteful manner, perhaps, but that is a matter of opinion) as the representative of a school of chemists, which numbers amongst its adherents many well-known names (as an example of which may be mentioned Sir Benjamin Brodie); the members of this school, though differing amongst themselves on certain details, yet agree on this main point, that they object to view the experimental facts of chemistry and the allied branches of knowledge, *solely* through the medium of one preconceived notion as to the ultimate nature of matter.

Speaking for myself, I fail to see the cogency of the reasons which lead a great number of modern chemists to the impression that matter can only be viewed as being made up of "atoms" of some sixty-five essentially different kinds; these atoms, when connected together in certain ill-defined ways, constituting the "molecules" of which the innumerable compounds now known are conceived as being made up. I admit willingly that this "atomic hypothesis," if once admitted, is in close accordance with very many physical generalisations (*vide* Maxwell's recent lecture on molecules); that it gives a clearer explanation of many chemical phenomena than has yet been afforded by any view based on other notions as to the ultimate nature of matter (*e.g.*, the notion that there is but one kind of primordial matter, all so-called elements and compounds being, as it were, allotropic modifications of this matter differing from one another in the amount of energy latent per unit of mass); and that, directly or indirectly, it has done immense service in extending the bounds of knowledge: but, notwithstanding the assertion of the President of the British Association, that there has not been shown to be "any inconsistency in the atomic theory, nor in the conclusions to which it leads," I yet venture to think that this "atomic hypothesis" is not capable of giving a clear explanation of many chemical phenomena now known to us, and that it is not consistent with other so-called Laws of Nature (*i.e.*, hypotheses that meet every case yet propounded by experiment or predicted beforehand).

To take a single case: there is no hypothesis that better deserves the term "Law of Nature" to be applied to it than Newton's fundamental postulate, that two very small portions of matter (and *ergo*, two atoms) attract one another with a force proportionate to the product of their masses, and inversely proportionate to the square of the distance between them. I fail, however, to see how the motions of molecules amongst themselves in diffusion, expansion, friction, &c., are explained in accordance with Newton's hypothesis; nor do I see how the evolution of definite quantities of heat during chemical reactions (*i.e.*, the transformation of certain amounts of atomic motion into molecular motion), and many other analogous phenomena, are accounted for by this "law of force" regulating the mutual action of atoms on one another. On this point I may be in error, if so, I am open to conviction, and will willingly recant my objection to the atomic hypothesis on this score when it is shown that the same hypothesis which accounts for the motions of celestial bodies will also account for those of ultimate atoms, the existence of such atoms being assumed.

Even then, however, I should still retain the conviction,

which I have elsewhere expressed, that in teaching the science of chemistry it is preferable, first, to enumerate the facts in language independent of any hypothesis, and then to enunciate the various hypotheses that have been and are held, showing how far each is in accordance or contradiction with the observed facts; rather than to mix up from the outset one particular hypothesis with the facts, so as finally to impress on the mind the manifestly erroneous conclusion that the facts have no existence apart from the hypothesis that more or less clearly explains them.

The President of the British Association states that the objectors to the atomic theory "are unconsciously guided by it." It may be within the memory of such of your readers as are interested in this matter, that some little controversy on this subject was carried on last year in the pages of the *Philosophical Magazine*. This ceased on my part from a conviction of the uselessness of continuing discussion with an antagonist who persistently ignored the main point at issue, *viz.*, the distinction between the meaning attached to the phrase "atomic theory" by Dr. Williamson and his disciples, and that applied to the term "atomic hypothesis" by myself; the former phrase being employed to indicate not merely what is commonly understood as a hypothesis, but also to connote a large number of purely experimental generalisations wholly distinct from the hypothesis propounded to account for them. That the atomic hypothesis (as these words are understood by the majority of chemists) is in any way whatever, consciously or unconsciously, involved of necessity in the calculation (from experimental data and arbitrary conventions) of a formula (*i.e.*, a set of symbols indicating in brief certain physical and chemical properties and reactions), is a point that I am wholly unable to see; but, on the other hand, the following quotations (samples of many that might be given as illustrations) demonstrate to my thinking that the habit of mixing up the known and the unknown by using defective language which embodies both forms of idea when the former only should be referred to, is productive of contradictory statements and of unphilosophical modes of thought.

"The so-called Law of Multiple Proportions has no existence apart from the Atomic Theory." (Williamson, *Journ. Chem. Soc.*, 1869, p. 339.)

"The Law of Multiple Proportions, being founded on experimental facts, stands as a fixed bulwark of the science, which must for ever remain true; whereas the Atomic Theory, by which we now explain this great law, may possibly in time give place to one more perfectly suited to the explanation of new facts." (Roscoe, "Elementary Chemistry," 1st edition, p. 54.)

"This important law (of multiple proportions) which was first clearly established by Dalton, was explained by him by means of his atomic theory." (Miller, "Elements of Chemistry," vol. i., p. 15, 1st edition.)

"The atomic theory . . . is the very life of chemistry." (Williamson, *loc. cit.*, p. 365.)

Sir Benjamin Brodie "agreed with Dr. Odling when he said that the science of chemistry did not require or prove the atomic theory." (*Ibid.*, p. 440.)

It is scarcely necessary to point out that the statements of Dr. Williamson are diametrically opposed to the juxtaposed quotations; that the first statement is in opposition to the opinion of most other chemists; and that these discrepancies arise from the abnormal meaning attached to the term "atomic theory" by Dr. Williamson.

For the reasons above stated, I have no wish to re-open a controversy on this subject; but the way in which my name is referred to in the article alluded to causes me to request space for the insertion of the foregoing remarks, so as to correct any possible misapprehension as to the effect of the eloquent presidential address at Bradford on the opinions of those who object to view facts *solely* through the medium of preconceived notions, no matter how attractive or how useful when judiciously employed.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Annual Meeting, April 29th, 1873.

E. W. BINNEY, F.R.S., F.G.S., Vice-President, in the Chair.

THE following Report of the Council was read by one of the Secretaries:—

The Council have the satisfaction to report that a further improvement has taken place in the financial position of the Society, the Treasurer's account showing that the general balance on the 31st of March last was £407 18. 4d., against £340 os. 3½d. on the 31st of March, 1872.

The number of ordinary members on the roll of the Society on the 1st of April, 1872, was 174, and 6 new members have since been elected; the losses are—Deaths, 4; resignations, 4; and defaulters, 3. The number on the roll on the 1st of April instant was, therefore, 169. The deceased members are John Francis, George Cliff Lowe, Samuel Emanuel Nelson, and Joseph Jordan.

Mr. George Cliff Lowe, whose death was the result of an accident in the United States, was known to many of our members for his general and accurate acquaintance with the natural sciences, but more particularly that of astronomy.

Possessing a love of knowledge for its own sake, and a comprehensiveness of mind to deal with other besides purely physical subjects, he took great interest in the leading philosophical questions of the present time, and his opinions were generally to be found on the side of progress. Although not a frequent contributor to the literature of science, Mr. Lowe had an acuteness of perception, combined with a degree of manipulative and artistic skill, which made his co-operation and judgment much valued and sought for by others.

We thus find Mr. Lowe's name associated with that of Professor F. C. Calvert, F.R.S., in a joint paper "On the Expansion of Metals and Alloys," published in the *Proceedings of the Royal Society*, vol. x., 1860. Mr. Lowe was also associated in business with our member Mr. Wilde as an electrical engineer, and suggested to him the plan of exciting a number of electro-magnetic machines by the current from one machine, instead of employing a separate exciting machine for each. With his philosophical attainments Mr. Lowe combined estimable moral qualities, the most conspicuous of which were the amiability of his character and the generosity of his disposition.

Mr. Joseph Jordan, F.R.C.S. Engl., was one of the oldest members of the Society, having been elected on the 19th of October, 1821. He was born in Manchester, and, with the exception of a short period when he was surgeon of the 1st Lancashire Militia, resided in Manchester all his life. He retired from active practice about nine years ago, when he was in the 76th year of his age. His name will be distinctly remembered as the founder of provincial medical schools. As early as 1814, he gave regular courses of lectures on anatomy, with demonstrations and dissections, to classes of medical pupils and students. He was the first provincial lecturer and teacher whose certificates were accepted and recognised by the examining bodies in London. The Apothecaries' Hall began to accept his certificates in 1817, and the College of Surgeons in 1821. In 1826 he built a medical school in Manchester at his own cost, and, besides its lecture hall, provided it with one of the most commodious and best-fitted dissecting-rooms in England, and transferred to it his own valuable museum, containing nearly 4000 anatomical specimens and morbid and other preparations. He subsequently placed this museum in the Manchester Royal School of Medicine. He devoted himself to the arduous duties of a

public lecturer for twenty years. On his retiring from the chair, a public dinner was given to him by his friends, in October, 1834, attended by almost every medical man of reputation in Manchester, and a handsome and valuable testimonial in silver plate was presented to him from his friends and pupils.

Mr. Jordan had further claims upon public regard as a large benefactor to suffering humanity by professional unpaid services. In his private practice, extending over more than fifty years, Mr. Jordan ever showed a special devotion to the relief of the sickness and suffering of the poor. His great professional skill, often unpaid, and even supplemented by a liberal purse, and that genuine kindness which ever doubles the value of a gift, won for him the blessings of thousands. Nor was his philanthropy less conspicuous in official positions. About 1819, he aided largely in founding the Lock Hospital for unfortunate women, of which he was the surgeon or consulting surgeon till he finally retired from practice. He was always a steady benefactor to the institution, in wise counsel and liberal donations. In 1835, he was appointed an honorary medical officer of the Royal Infirmary, and long filled the honourable position of its senior surgeon with the highest credit to himself and with great benefit to the institution and the community at large. Within its walls he often performed some of the greater, as well as the more delicate, operations of surgery; his remarkable nerve and steadiness and precision of hand admirably qualifying him for these duties. He invented a most beautiful little lamp to obtain a magnified view of the membrane tympani and other organs, for which the Society of Arts awarded their silver medal. His clinical lectures in the hospital wards always attracted a large and attentive following of the pupils and students, and a few years ago a very numerous signed testimonial was presented to him by the pupils of the Royal Infirmary for these lectures. He was a most eloquent and interesting lecturer, and his great and long experience enabled him to illustrate his lectures with cases bearing upon the subject, which rivetted the attention and increased the knowledge of his hearers.

Mr. Jordan was a valued contributor to medical science by a new method of treating false joints. A difficult class of surgical cases is presented when the fractured surfaces of bone refuse to reunite, or else unite so badly as to cause great suffering and even loss of the use of a limb. For the cure of these so-called "false joints," and the effecting of a speedy, safe, and satisfactory reunion of the fractured bones, Mr. Jordan, in the year 1854, invented and applied a new and exceedingly simple mode of treatment. His plan was recognised not only by his professional brethren in Manchester, but in June, 1856, the eminent Paris surgeon, Professor Nelaton, in a public lecture to his class, described the method as "a happy innovation, and one capable of receiving numerous applications." The priority of Mr. Jordan's claim to this invention was beyond doubt. Finding, however, that a French surgeon was introducing the method as his own, Mr. Jordan proceeded to Paris in 1860, where he published in French a treatise, illustrated with three plates, entitled "Traitement des Pseudarthroses par l'Autoplastique Periostique," which not only effectually extinguished any rival claim, but comprised a full and clear exposition of the mode of treatment in all its successive stages, and gave to the author a European reputation.

It was at one time proposed that some mark of her Majesty's favour should be solicited by Mr. Jordan's friends, to honour one who had conferred so much credit upon his profession in Manchester, and so much advantage upon the community at large; but the modesty of the veteran self-sacrificing surgeon shrunk from this distinction, and at his instance the movement was stopped.

In the last annual report it was stated, with reference to the benefaction which the late Natural History Society provided for the promotion of the study of natural history in Manchester, under the guardianship of the Literary and Philosophical Society, that the Owens College would at once proceed to endeavour to sell the Peter Street site, to

be delivered up in June, 1873, for money or for rent, as may seem best. In the latter case, it had been agreed between the Commissioners and the College that the College should pay £60 per annum as interest at 4 per cent on £1500 until the principal shall have been paid over to the Society. The Council have now to report that the Peter Street site has not yet been sold, but on the 20th of November last a letter was addressed by Mr. Darbishire to Mr. H. A. Hurst, the treasurer of the Microscopical and Natural History Section, stating that, by an arrangement made on that day between the Commissioners of the Peter Street Museum and the Owens College, the Museum Trust in the hands of the College will pay to the Philosophical Society, for the present, interest upon the sum of £1500 at 4 per cent from that date. The first half-yearly payment will therefore become due on the 20th of May next.

At a meeting of the Council held on the 7th of January last, a committee was appointed to consider and report upon the desirability of incorporating the Society, and of acceding to an application of the Manchester Geological Society for permission to hold its meetings and keep its library within this society's buildings. Resolutions embodying the recommendations of this committee will be submitted for the approval of the members of the Society.

In May of last year, Dr. R. Angus Smith, F.R.S., a vice-president of this Society, attended on behalf of the Society the centenary celebration of the foundation of the Royal Academy of Sciences of Belgium, and a medal has this day been received commemorative of this interesting event.

The following gentlemen were elected officers of the Society and members of the Council for the ensuing year:—
President—James Prescott Joule, LL.D., F.R.S., F.C.S., &c.

Vice-Presidents—Edward William Binney, F.R.S., F.G.S.; Edward Schunck, Ph.D., F.R.S., F.C.S.; Robert Angus Smith, Ph.D., F.R.S., F.C.S.; Rev. William Gaskell, M.A.

Secretaries—Henry Enfield Roscoe, B.A., Ph.D., F.R.S.; Joseph Baxendell, F.R.A.S.

Treasurer—Thomas Carrick.

Librarian—Charles Bailey.

Of the Council—Robert Dukinfield Darbishire, B.A., F.G.S.; Osborne Reynolds, M.A.; William Boyd Dawkins, M.A., F.R.S., F.G.S.; Balfour Stewart, LL.D., F.R.S.; Alfred Brothers, F.R.A.S.; Rev. Brooke Herford.

MICROSCOPICAL AND NATURAL HISTORY SECTION.

April 21st, 1873.

Professor W. C. WILLIAMSON, F.R.S., President of the Section, in the Chair.

Mr. JOHN BARROW read a paper "*On the Use of Naphthalin in Section Cutting.*"

I wish to bring before the notice of the members, and those microscopists who are interested in cutting sections of soft or delicate tissues, the use of naphthalin as a support for such tissues in the section cutter.

The advantages obtained by the use of naphthalin over wax and other bodies recommended for this purpose are—A low fusing-point, absence of contraction in the cutter, very little injury to the edge of the knife, and very ready solubility after cutting in benzol or spirit, so that the substance is removed at once from the section without injury.

Naphthalin is a body not very generally known outside the works of the tar-distiller or colour-maker, so that possibly some of the Members may not be able to obtain samples readily, but I shall have pleasure in supplying it to any of our own members.

Professor WILLIAMSON recommended an admixture of wax and oil with the naphthalin, and stated that the knife cuts better with this addition; he also exhibited some extremely beautiful longitudinal and cross sections made in this way.

CORRESPONDENCE.

PHOSPHATES OF IRON AND ALUMINA IN MANURES.

To the Editor of the Chemical News.

SIR,—To all farmers and agricultural chemists the real value of soluble and precipitated phosphates of iron and alumina, as compared with that of the corresponding lime compounds, is a question of very great interest. The various native phosphates contain more or less ferric oxide and alumina, free or combined, part of which, during the superphosphating process, is rendered soluble; and the proportion thus dissolved is not inconsiderable when, as at present, the high prices of raw material and labour necessitate the use of as much acid as possible consistent with dryness, so as to leave little insoluble phosphate. The ferric and aluminic oxides are thus more apt to be dissolved along with the phosphates and carbonate of lime.

It is admitted very generally that precipitated phosphate of lime is equal in real value to the soluble form of that compound; in fact, that as soils contain carbonate and humate of lime, the soluble monocalcic phosphate is transformed almost immediately into the very sparingly soluble dicalcic salt. More readily so will the soluble monoferric phosphate revert to the insoluble form under the same circumstances. Whether the soluble iron in manures exists in combination with phosphoric or sulphuric acid is of no moment, as the lime in the soils will so act on monocalcic phosphate and sulphate of iron as to give insoluble ferric phosphate.

Is this precipitated ferric and aluminic phosphate capable of ready assimilation in the soil? Many chemists will point to its comparative insolubility in carbonic acid water as supplying a negative answer, but I am not quite satisfied with this conclusion. In the soil there are many substances besides carbonic acid playing a part in the dissolving of insoluble plant food, such as carbonates of lime and magnesia, alkaline chlorides and sulphates, ammoniacal salts, hydrated silicates, humus, &c. It would be interesting to know whether any experiments have been made to test the point. It is well known that under the influence of water containing carbonic acid all silicates are more or less readily decomposed, the bases going into solution as carbonates and soluble silicates. According to Zöller, soil drainage contains 9.34 to 17.46 grs. silicic acid per 1,000,000 grs. resulting from such action. Is it at all unlikely, might it be asked, that between these products and ferric and aluminic phosphates such a decomposition might arise as would result in the formation of a soluble phosphate? Alkaline silicates decompose these phosphates so completely as to be employed in the quantitative separation of the phosphoric acid from its base, the acid being rendered soluble. In the soil drainage we have, if not alkaline silicates, silicic acid and alkaline and earthy carbonates. Might we not have, in short, silicic acid and a bicarbonate so acting on phosphate of iron as to form a soluble phosphate and silicate of iron? Besides, it is by no means unreasonable to suppose that all soluble phosphates of lime and magnesia applied to the soil become very soon converted into ferric and aluminic phosphates. All fertile soils contain a practically unlimited quantity of active ferric and aluminic hydrates, and analyses of drain-water from various soils show quantities in solution varying from 1.32 to 8.26 parts per million. Here we have the conditions necessary for the conversion—an almost unlimited quantity of the precipitant, and a liquid able to dissolve it.

You have readers in all parts of the country, indeed on both sides of the Atlantic, to whom this question is one of great practical importance, and I shall be amply rewarded for my pains if these remarks should originate a thorough and exhaustive discussion of the subject in your columns.—I am, &c.,

TRUTH SEEKER.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 728.

PRELIMINARY INVESTIGATION OF THE FLUORESCENT AND ABSORPTIVE SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON, Ph.D.,
(Continued from p. 167).

Arsenates of Uranium.

We have examined the following compounds of arsenic acid with the sesquioxide of uranium:—

From this—which must, however, be regarded as quite too limited a range of experiment for so extensive a deduction—it would seem as if the compound of uranic oxide with arsenic acid were peculiarly fixed and inflexible in the relations which we have now under review. We obtain from these four compounds, at all events, but one spectrum of fluorescence and one of absorption. The three first-named fluoresce with various degrees of brightness, but with the same bands; which are, moreover, very characteristic as compared with those of other salts. Zeunerite shows no fluorescence.

The bands of these spectra have the appearance of flat narrow ribbons, with little of that graduation on the edges which is observable with the other spectra. They appear as if displayed against a partially illuminated back-ground whose uniform tint is broken by a shade on the more refrangible side of each band. 1 of Fig. 8 will give some idea of this.

FIG. 8.

Arseniate and Carbonate.

FIG. 9.

Arseniate and Carbonate.

Absorption-Bands.—All four of the substances named above give the same absorption spectrum, which is distinguished by the same characteristic noticed in the fluor-

* Communicated by President Morton.

escent spectrum of these salts, namely, the presence of narrow well-defined flat bands. Above 110, where the general absorption begins, the bands not only seem darker, but more blended on their edges. In Fig. 9 the first spectrum will indicate this.

Uranic Carbonates.

Carbonate of uranium, *per se*, does not exist, but in combination with the alkaline carbonates forms finely crystallised, not very soluble double salts. The ammonium salt, $U_2O_3 \cdot CO_2 + 2(NH_4O \cdot CO_2)$, has been mentioned; the corresponding compounds of sodium and potassium are obtained by dissolving the uranates of these bases in warm strong solutions of their respective carbonates. The uranic carbonates thus far examined are the following:—

They all fluoresce faintly, their relative brightness being in this order—Ammonio-, sodio-, and potassio-salt, in decreasing intensity. In character the spectra of these salts very much resemble those of the less brilliant double acetates, though they have a stronger light in a narrow line near the more refrangible edge of each band. The positions of the bands of these three salts were not distinguishably different with the methods employed in this examination, and may be seen from 2 in Fig. 8.

The absorption spectra of the ammonio- and potassio-salts are indistinguishable from each other, and from the solutions of any of the three salts; 2 in Fig. 9 shows the absorption spectrum of the sodio-salt, and 3 that of the other salts and of the solutions. The absorption-bands of all these carbonates are remarkably distinct and strong. Stokes first drew attention to them, and suggested their use as a means of recognition (*Phil. Trans.*, 1851, Part II., p. 522).

The thing that strikes the attention at once on seeing the absorption spectrum of the carbonates is the prominence of the three strong black bands at about 105, 115, and 125, which stand out clearly on a light back-ground, the general absorption which commences above this making the higher bands far less prominent.

Oxychlorides.

The salts of this class which we have thus far examined are the following:—

The uranic oxychloride, $U_2O_2Cl + HO$, in various states of hydration not yet determined.

Ammonio-uranic oxychloride,—

Potassio-uranic oxychloride,—

We have not as yet succeeded in obtaining other double salts of this class. The method of preparation is simply to mix the respective chlorides in atomic proportions with water and excess of hydrochloric acid, and place in a desiccator. Sometimes, however, we have found that under these conditions the salts would crystallise out separately, again and again, without forming a compound. It, however, occurred to us that, if a ready-formed crystal of the double salt were placed in such a solution, it would act as a determining centre, around which like material would group itself. In all cases where this plan has since been tried, it has succeeded admirably. Thus, a mixture of ammonio and uranic oxychlorides, which had been standing for months without forming a particle of double salt, yielded a large crop of crystals within twenty-four hours after the addition of a few ready-formed crystals, and then continued to produce nothing but the double salt.

Uranic Oxychloride, $U_2O_2Cl + HO$.—A neutral solution of the above in a desiccator forms an opaque yellow mass having a moderate fluorescence, and yielding the spectrum

shown in 2 of Fig. 10. This is the substance generally known as the uranic oxychloride, or, in commerce, as uranic chloride. The general character of its spectrum is that which may be regarded as normal to uranic salts—a series of rounded bands terminating most abruptly on the upper edge. In transmitted light, it produces a very marked absorption spectrum, which is shown at 1 of Fig. 11. When the neutral oxychloride is dissolved, it forms a rich orange solution, which has a very great general absorption, and shows some bands; it is almost devoid of fluorescence. The addition of a little hydrochloric acid greatly reduces its colour, and, as with the uranic acetate, clears up its spectrum, which then shows the bands exhibited in 3 of Fig. 11. These same bands are shown by the solutions of the ammonio and potassio double salt, and lead us to conclude that the double chlorides, like the double acetates, only exist as such in the solid or crystallised state. If the uranic oxychloride is allowed to crystallise from a very acid solution in a desiccator, it will form a transparent yellow mass, whose spectrum will be of the duplex character indicated in 4 of Fig. 1. This we have little doubt indicates the presence of two hydrates, but it is curious to observe how regularly this spectrum appears whenever the uranic oxychloride crystallises from an acid solution. We encountered it constantly in our unsuccessful attempts to form double salts.

Fig. 10.

Oxychlorides.

Fig. 11.

Oxychlorides.

Ammonio-Uranic Oxychloride, $U_2O_3Cl + NH_4Cl + 2HO$.—Though this substance is often so difficult to form, as has been already stated, yet, once formed, if there is a slight excess of hydrochloric acid present, it may be fused, and will crystallise instantly on cooling. If kept in a fused state until a partial decomposition has taken place, an opaque yellow body is formed, which fluoresces very brightly, and yields a continuous spectrum. The normal salt is, perhaps, one of the most beautifully fluorescent in the entire series, and it yields a spectrum equally remarkable. This is represented at 1 of Fig. 10. Each band, as we may say, is here made up of from three to five narrow stripes variously shaded, and this, combined with their rich colouring produces an effect of wonderful beauty. The absorption spectrum of this salt, also of a somewhat composite character, is represented in 2 of Fig. 11.

Potassio-Uranic Oxychloride, $U_2O_3Cl + KCl + 2HO$.—This salt, in all its fluorescent relations, so closely resembles the ammonio salt just described, that it is only necessary to note this fact, and say that all its bands are a very little raised in the spectrum, but this difference is too small to be represented in a cut on the scale here employed.

(To be continued.)

ON THE SPONTANEOUS ASCENT OF LIQUIDS IN VERY NARROW SPACES.

M. DECHARME, having a short time since studied the ascent of a large number of liquids in capillary tubes, has recently experimented on the ascent of these liquids in porous paper, with the view of ascertaining whether they ranked in the same order, in this case, as regards height and velocity of ascent. The general results are as follows:—

(1). The ascending movement of liquids in strips of blotting-paper, compared with that in capillary tubes, presents essential differences, as well as numerous similarities. The curves obtained in both cases resemble each other in being sensibly divergent from parabolas, and tending, in the latter part, especially to the hyperbola; but in the blotting-paper the phenomenon is more complex than in the tubes, first from the influence of the hygrometric state of the air, and next because there is sometimes dialysis as well as capillarity.

(2). Each liquid has a velocity of ascent proper to it (papers of constant size being used in each case, and all other conditions being the same). The strips used were 15 or 30 m.m. in breadth, and all from the same sheet.

(3). For different liquids, in the same conditions, the velocities of ascent are not in direct proportion to the height ultimately reached. Thus non-volatile substances, as concentrated acid or saline solutions, and substances largely absorbent of water, sometimes rise slowly; but their movement may continue for days, or even for weeks.

(4). The velocity is, moreover, neither in inverse proportion to the total duration of the movement, nor simply proportional to the density of the liquid. The law depends on other elements, such as temperature and hygrometric state. The annexed curves illustrate these statements.

(5). With capillary tubes, only one liquid was met with which had a velocity constantly superior to that of pure water; it was an aqueous solution of chlorhydrate of ammonia. With the papers, more than forty liquids have been found in a total of 207 (i.e., about a fifth), having both a velocity and a final height superior to that of water. Among these may be cited chlorhydric, nitric, oxalic, tartaric, and citric acids; chlorides of calcium, zinc, and lead; chlorhydrate of ammonia; nitrate, bichromate, oxalate, urate, cyanurate, and oxalurate of ammonia; iodide and bromide of ammonia; chlorate, perchlorate, persulphate, and bisulphate of potash; sulphocyanide, bromide, and cyano-ferrate of potassium; sulphate of soda, &c.

(6). For the same liquid, all other conditions equal, the velocity and the capillary height increase with the breadth of the paper.

(7). For the same liquid, and the same breadth of paper, but for strips of a thickness double, triple, quadruple, &c. (multiple strips formed by superposition of several equal strips), the capillary velocity, and the duration of the ascent increase very sensibly with the thickness.

(8). A slight pressure exerted on these multiple strips, better insuring their contact, favours the ascending movement; but, beyond a certain limit of strength, pressure as a sufficiently extended surface diminishes the velocity of ascent, and may even arrest the movement altogether.

(9). The inclination of the paper has a positive influence on the velocity, the length of course run by the liquid, and the total duration of the movement. In every case there is not a proportionality between the heights or the velocities observed and the variable elements, breadth and thickness of paper, pressure, &c.

(10). For all liquids, the velocity of ascent increases with the temperature. Still, if at the beginning of the movement such increase appears, it is presently counter-balanced and ruled by the evaporation, which retards, and

at length completely arrests, the ascent of the liquid, especially where the latter is somewhat volatile. The influence of temperature varies much with the nature of the liquids.

(11). The hygrometric state of the air plays an important part. The more humid the air, comparatively, the greater the velocity and the duration of ascent, and the height finally reached.

What is here said about water applies to many other liquids, especially to those which are very volatile, or to solutions of very hygrometric substances.

Strips soaked, by capillarity, with the following substances, have remained humid during several months in summer:—

Cyanide of potassium.	Nitrate of uranium.
Sulphocyanide of potassium.	" silver.
" ammonium.	Pentachloride of potassium.
Chloride of ammonium.	Hyposulphite of potassium.
" calcium.	Hypophosphite "
" magnesium.	Phosphite of ammonia.
" zinc.	" potash.
Sesquichloride of chromium.	Sulphite of potash.
Bromide of lime.	Bisulphite of potash.
Nitrate of lime.	Acetate of potash.
" copper.	Caustic potash.

The following example gives an idea of the influence of degree of humidity of the air on the ascent of water in strips of 15 m.m. breadth:—

		Time (in hours).										
		1	1.	2.	3.	4.	4½.	5.	10.	20.	40.	51.
Heights in m.m.	Air pretty dry..	81	104	125	132	136	137	(End of movement.)				
	Air very humid	135	166	180	195	197	198	199	204	214	228	232

Chlorhydric and nitric acids and half diluted sulphuric acid have remained in the papers six or seven days, the temperature being 15° to 20°. Chloride of gold completely blackened the strip, which soon fell to pieces, all remaining humid, however, a long time. The strip soaked with sulphocyanide of potassium remained humid throughout its length, 45 centimetres, during more than six months, beyond which the experiment did not continue.

(12). Another cause often comes to act as an obstacle to the ascent of saline solutions, viz., the crystallisation which takes place in the paper from evaporation of the liquid. An example of this is chlorhydrate of ammonia, which, in moist air and moderate temperature, shows at first a velocity equal, and even sometimes superior, to that of half diluted chlorhydric acid, which has generally the maximum velocity of ascent; but, if the surrounding air is pretty dry, the salt in a day or two crystallises in layers, more or less thick, in the middle part of the strip, thus retarding the movement, and at length arresting it.

This applies also to saturated solutions of crystallisable hygrometric substances, which, without having the velocity of chlorhydrate of ammonia, show similar variations.

It results, from these various disturbing influences, that the ascending movement of a liquid in a strip of blotting-paper may be modified by external circumstances in such a way that, for a certain number of liquids, the order of velocities of ascent, that of duration, and that of final height, may be reversed.

En résumé, the little volatile, very soluble, very hygrometric liquids, which do not crystallise in the blotting-paper, are those which rise the highest, if not the most quickly.

The order of capillary heights, that of velocity, and that of total duration, may therefore be, and in fact are, quite different for the same liquids experimented on successively in capillary tubes and in strips of blotting-paper. The laws governing the two phenomena are different.

It appears, from experiments made on a great number of liquids, differing much both as to chemical composition and physical properties, that with capillary tubes the aqueous solution of chlorhydrate of ammonia and water are in the first rank for velocity and final height; while in strips of blotting-paper these two substances are surpassed in both respects; in the second, especially, by dilute acids, alkalies, and several potassic, sodic, calcic solutions, &c. Further, in strips of paper, chlorhydric acid has the greatest velocity, and generally reaches the maximum height. Silicate of potash, which, with capillary tubes, stood between glycerin and olive oil, is here at the very bottom of the scale; its movement is almost *nil*; it only, indeed, reaches about 4 m.m. height in the blotting-paper.

From the preceding results relating to ascent of liquids in multiple strips, the following inferences are drawn:—

(1). They explain how liquids, water in particular, with matter held by it in solution, rises to such great height in porous building materials of a house, where the foundations rest in a damp soil. It is not an extraordinary thing that, after some time, the presence of moisture and saline matters should be detected, not only on the ground floor, but on the first, and even the second; the liquid ascending in capillary substances of great thickness, and not subject to much evaporation.

(2). The vessels of plants, with their numerous anastomoses, and the permeability of the tissues composing them, are rather comparable to the superposed strips of blotting-paper than to capillary tubes. It is not surprising that the greater part of the saline solutions containing solids fit for their nutrition rise in the vessels to heights much greater than water would do, and also more quickly.

It is not necessary, then, to have recourse to an extreme fineness of vessels, to explain the ascent of liquids in the tissues of plants. It is sufficient to remark that the saline solutions which naturally exist in the soil rise higher than pure water; sometimes to double the height, *e.g.*, the following salts:—Nitrate, sulphate, carbonate, bicarbonate of potash, nitrate of lime, carbonate of soda, chlorides of potassium and of sodium.

A. B. M.

THEORY AS TO THE FORMATION AND PROPERTIES OF OZONE.

By R. LAMONT.

WHEN phosphorus is allowed to oxidise in air, or oxygen gas, phosphorous pentoxide and ozone result. An atom of oxygen cannot exist in the free state, but a molecule can, which in this case consists of two atoms (O-O). Phosphorous pentoxide consists of a molecule of phosphorus combined with two molecules + an atom of oxygen. When phosphorus is left to oxidise in oxygen, the molecule of phosphorus combines with two molecules of oxygen, but, this not being sufficient to form the pentoxide, it must have another atom of oxygen, which it can only get by splitting up a molecule of oxygen—one of the resulting atoms combining with the phosphorus, the other atom going to a molecule of oxygen to form ozone (O-O-O). If the ozone which has been formed is allowed to remain in contact with the phosphorus, it is decomposed thus—

The powerful oxidising properties of ozone may be accounted for by supposing that the three atoms of oxygen are so loosely combined that, when it comes in contact with an oxidisable substance, one of the atoms combines with this substance, the other two going to form a molecule of oxygen.

ANALYSIS OF GREAT SALT LAKE WATER.

By H. BASSETT.

HAVING a small quantity of the above water placed at my disposal by Dr. W. Marcet, F.R.S., who collected it himself last August, I thought an analysis might be of interest, especially as I have not found any account of it in books of reference. The water has a slight alkaline reaction, and a specific gravity of 1.102 at 17°.

Total solid residue, in 100 parts, by weight = 13.67.

In 100 Parts by Weight.

Chlorine	7.36
SO ₄	0.88
Sodium	3.83
Potassium	0.99
Calcium	0.06
Magnesium	0.30

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 224).

LET us now pass on to the mode of obtaining electricity from chemical action. Before doing so a phenomenon should be noticed, which disturbs results very seriously, and which is, at present, not understood. Here is some copper wire, covered with cotton, coiled from end to end, say five or six times along this large bobbin of wood.

Within the bobbin is a larger hole than usual. The two ends of this wire so coiled are connected with the reflecting galvanometer. The reflected light from this lamp is now visible and stationary upon the screen. You are aware that motion of that reflected speck of light will be the consequence of electricity passing through the coils of the galvanometer. Now, observe that, without either chemical or physical agency acting upon or in contact with the wire, we shall obtain a manifestation of electrical disturbance within the copper wire. Let the end of this steel magnet be introduced within the bobbin: you see that the speck of light immediately moves. Except in this manner, copper does not manifest electrical properties. Again, if the other end of the steel magnet be brought within the bobbin, you see the speck of the galvanometer moves in an opposite direction. Thus may be shown one form of electrical induction.

Now, with that phenomenon we are perplexed. This property of induction manifests itself at times and in ways of which we know nothing. For example, if a copper wire were laid upon this floor, and another copper wire were laid parallel to it on the floor below; and if any current of electricity passed through the wire on this floor, the one below would answer to it, although there was not any apparent contact or communication between them.

The laws which govern such electrical manifestations as these are very partially understood, and therefore the measurements of the results of these laws are for general use almost valueless. We must, however, for the present assume that the nature of the phenomena of electrical induction is clear.

The next stage in obtaining electricity is by means of what is called a galvanic cell. Such a cell usually consists of two different metals and one or two liquids. Whatever may be the arrangement, the electricity developed may be estimated by the intensity of chemical affinity during the process and at the time of the measurement. But the whole of this question of chemical affinity must now be assumed, and some of the affinities explained in the last lecture are probably the chemical affinities operating in this cell. A chemical action takes place upon a square inch of one plate, and it is met by an action upon a square inch of the other; therefore, on every square inch an action is produced. Between the two plates there is something (say the liquid) which causes the action; it is, in fact, the presence of this liquid which calls the chemical affinities into play.

A word must now be introduced which will often occur during the lecture, and it is one which performs an important part in the measurement of electricity of the character which men utilise, *i.e.*, resistance. Indeed, this resistance to the free passage of an electric current is now our chief business. Whilst the size of the plates in these cells is increased, the resistance to the free course of the manifested electricity is not decreased. Thus, for instance, from a square inch of one plate there is a current of electricity meeting or co-operating with that developed from a square inch of the opposite plate. Whatever may be the energy of the chemical affinity upon one square inch, it is met by the energy of the chemical affinity upon the opposite square inch of the other, and that energy has to overcome the resistance of the liquid between them. Now, then, assume that each of these plates is enlarged by the addition of another square inch. This introduces an additional quantity of liquid, and we have to overcome the resistance of this liquid. The difficulty of overcoming the resistance of the intervening liquid is such that, however much we multiply the number of square inches, we also introduce more liquid, and, by so doing, add further electrical resistance. Hence, however large may be the plates, we do not overcome the resistance more easily. That led to the contrivance of thus coupling up in what is called "a series" in the form you see here, that which is familiar under the name of a cell-battery.

It may perhaps make clear what is a difficulty to many minds, if an attempt be made to explain how it is that as

* The Cantor Lectures, delivered before the Society of Arts.

electrical current which passes when cells are coupled-up "in series," that is, one after the other, is more intense than when they are combined as one large single cell.

Supposing these two plates, each 1 square inch in area, were the only two concerned, therefore there would be a certain resistance to be overcome. The chemical affinity of one such combination not only overcomes that resistance, but leaves a surplus of electricity, which surplus is said to run along the outside wire, and may produce what we call a telegraphic dispatch. Now, suppose that, in addition to those two plates, there are two others of the same size and material in a cell behind them. Between these second plates there is also a resistance similar to that between the first two. Those two second plates, however, also produce a surplus. Now, as that surplus passes over, it continues its way through the previous plates and wire, and the consequence is that, when once the resistance of its own cell has been overcome, the surplus electricity can pass through the other cells without any resistance, and, therefore, we are enabled to add the surplus of one cell to the surplus of the next, and so on. Hence, when combined in the form in which they are combined in this battery, we are manifestly enabled to pass along the connecting wire successive equal amounts of electricities, and these, flowing so very closely behind each other, produce an effect upon any resistance similar to that produced upon a slab of marble or of glass by the forcible driving against it of small grains of sand in a continuous stream. These grains penetrate, and, as it were, bore holes even in hardened steel; so these successive electricities are, as it were, continuous, and thereby overcome great resistances. It may, in connection with this, be remarked that, perhaps, in some such way as now described, the mighty energies of affinity may be accomplished by this clashing of millions upon millions of atoms and molecules. This may explain how and why it is that these cells thus arranged "in series" are under certain circumstances more effective than when the same amount of liquid and metallic elements operate as one cell only.

Electricity thus, or by other means at our disposal, is now to be measured. Two things are especially before us now. One to make clear how this measurement is made; the other to endeavour to make clear how the resistance of various bodies, be they wires or liquids, is also measured.

This electricity is measured in a very simple way. All the apparatus is here, but as it would take too long to show experiments in detail, perhaps you will kindly accept a statement of facts instead of a visible reproduction of them. In these cells is being produced a quantity of electricity, which is to be measured, much as sugar is measured by the pound, or liquids by the quart. The way it is measured is either by the chemical decompositions that it can produce, or by the amount of heat it can develop, or by other means, as, for instance, its effect upon the magnet in a given time.

This seems a convenient opportunity for directing attention to a galvanometer, which is arranged upon a plan by which is shown the amount of decomposition effected by the current indicated by the place of a needle on the dial. The gentleman who designed it had in view only a manufacturer's requirements. The measurement effected by such a galvanometer is not of that character with which this lecture is to be concerned, and therefore further reference to this particular one is not requisite.

To consider a mode of measurement we must recur to those elements—mass, space, and time. The apparatus on which my hand now rests consists of a wooden ring, about 10 inches in diameter, having coils of copper wire round it. Within this circular box with a glass top is a small magnetised steel needle. Now, the small steel needle assumes a certain position in consequence of the influence of terrestrial magnetism. Such an influence as this is not unlike a stream of water in a brook upon a short stick, one end of which is tied to a stake by a

string. So long as the stream flows steadily past the stick it is retained in the same position. Let a disturbance take place in the evenly flowing water, and the stick will no longer retain either steadiness or direction. Suppose, now, that this needle is retained in a certain direction by the influence of what we may call the stream of terrestrial electricity flowing through the atmosphere of this room. (That such a stream is so flowing through the atmosphere shall be made apparent presently.) From these four cells of a galvanic battery a current of electricity may be caused to pass along the wire which surrounds this wooden ring. The arrangements are made, and such a current is now passing. What is the consequence? The even flow of that which retained the needle is disturbed, and the needle answers as the stick in the water would have done to the disturbing causes. Clearly the nature and extent of the invisible disturbance may be estimated—indeed measured—by the motions of the visible needle, just as a new position assumed by the stick would measure the disturbing influence on the stream.

The promise to let you have proof that there are currents of electricity passing through the atmosphere of this room may now be redeemed. Here is a circular wooden ring, with wire round it as before. You may notice that it can be turned as a looking-glass in its frame. The ends of the wire coiled round it are now connected with the wires of the galvanometer, the mirror of which reflects that speck of light on the screen. The looking-glass mounted ring is placed in reference to the (so-called) current of electricity always passing through the atmosphere, that were there a glass in the frame the current would beat upon that glass. If the frame be turned one-fourth round, then the current will pass parallel to the face of the frame. Or thus:—If the frame of the wire-enclosed ring be placed parallel to the direction of this magnetised needle, then the current of electricity through the atmosphere of this room is passing parallel to the ring. To move it, therefore, from this position to one at right angles to it, it is clear that the circumferential wire must, as it were, cut the stream of electricity, if there be one. Now, so cutting it, there will be a disturbance in the electrical condition of the wire, which may be manifested by a motion of that speck of light. Observe now, that every motion of the frame causes a motion in the needle of that galvanometer, which is placed on a stand far removed from the table on which the motion of the frame takes place.

The two experiments now made may satisfy you:—

(1). That there is what, for want of another name, we may call a current of electricity passing through the air; (2) that disturbance of the uniform quiet flow of this current may be caused; (3) that this needle is sensitive to such a disturbance; and (4) you will perhaps accept my word for that which time alone prevents being illustrated, viz., that the amount of this disturbance may be measured by the needle—that is to say, the greater the disturbance the further will the needle be moved from its original position.

It will be obvious to all that the amount of motion in the needle for any given disturbance will depend upon its sensitiveness. Hence, two needles may or may not move equally from the same cause. A mode of measurement, therefore, which depends upon an artisan's capability to make either unit jars or needles equally sensitive cannot be one to be much relied upon. There is, however, a relationship between the motion of the needle and a totally different mode of absolute measurement of the quantity of electricity that may pass in a unit of time, which solves the difficulty now expressed.

The usual apparatus for the decomposition of water by an electrical current is standing here. It is in consequence of completing the wire circuit from this combination of four cells that decomposition takes place. The bubbles are rising regularly and rapidly. Patient

It is not necessary, then, to have recourse to an extreme fineness of vessels, to explain the ascent of liquids in the tissues of plants. It is sufficient to remark that the saline solutions which naturally exist in the soil rise higher than pure water; sometimes to double the height, *e.g.*, the following salts:—Nitrate, sulphate, carbonate, bicarbonate of potash, nitrate of lime, carbonate of soda, chlorides of potassium and of sodium.

THEORY AS TO THE FORMATION AND PROPERTIES OF OZONE.

By R. LAMONT.

WHEN phosphorus is allowed to oxidise in air, or oxygen gas, phosphorous pentoxide and ozone result. An atom of oxygen cannot exist in the free state, but a molecule can, which in this case consists of two atoms (O-O). Phosphorous pentoxide consists of a molecule of phosphorus combined with two molecules + an atom of oxygen. When phosphorus is left to oxidise in oxygen, the molecule of phosphorus combines with two molecules of oxygen, but, this not being sufficient to form the pentoxide, it must have another atom of oxygen, which it can only get by splitting up a molecule of oxygen—one of the resulting atoms combining with the phosphorus, the other atom going to a molecule of oxygen to form ozone (O-O-O). If the ozone which has been formed is allowed to remain in contact with the phosphorus, it is decomposed thus—

The powerful oxidising properties of ozone may be accounted for by supposing that the three atoms of oxygen are so loosely combined that, when it comes in contact with an oxidisable substance, one of the atoms combines with this substance, the other two going to form a molecule of oxygen.

ANALYSIS OF GREAT SALT LAKE WATER.

By H. BASSETT.

HAVING a small quantity of the above water placed at my disposal by Dr. W. Marcet, F.R.S., who collected it himself last August, I thought an analysis might be of interest, especially as I have not found any account of it in books of reference. The water has a slight alkaline reaction, and a specific gravity of 1.102 at 17°.

Total solid residue, in 100 parts, by weight = 13.67.

In 100 Parts by Weight.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 224).

LET us now pass on to the mode of obtaining electricity from chemical action. Before doing so a phenomenon should be noticed, which disturbs results very seriously, and which is, at present, not understood. Here is some copper wire, covered with cotton, coiled from end to end, say five or six times along this large bobbin of wood.

Within the bobbin is a larger hole than usual. The two ends of this wire so coiled are connected with the reflecting galvanometer. The reflected light from this lamp is now visible and stationary upon the screen. You are aware that motion of that reflected speck of light will be the consequence of electricity passing through the coils of the galvanometer. Now, observe that, without either chemical or physical agency acting upon or in contact with the wire, we shall obtain a manifestation of electrical disturbance within the copper wire. Let the end of this steel magnet be introduced within the bobbin: you see that the speck of light immediately moves. Except in this manner, copper does not manifest electrical properties. Again, if the other end of the steel magnet be brought within the bobbin, you see the speck of the galvanometer moves in an opposite direction. Thus may be shown one form of electrical induction.

Now, with that phenomenon we are perplexed. This property of induction manifests itself at times and in ways of which we know nothing. For example, if a copper wire were laid upon this floor, and another copper wire were laid parallel to it on the floor below; and if any current of electricity passed through the wire on this floor, the one below would answer to it, although there was not any apparent contact or communication between them.

The laws which govern such electrical manifestations as these are very partially understood, and therefore the measurements of the results of these laws are for general use almost valueless. We must, however, for the present assume that the nature of the phenomena of electrical induction is clear.

The next stage in obtaining electricity is by means of what is called a galvanic cell. Such a cell usually consists of two different metals and one or two liquids. Whatever may be the arrangement, the electricity developed may be estimated by the intensity of chemical affinity during the process and at the time of the measurement. But the whole of this question of chemical affinity must now be assumed, and some of the affinities explained in the last lecture are probably the chemical affinities operating in this cell. A chemical action takes place upon a square inch of one plate, and it is met by an action upon a square inch of the other; therefore, on every square inch an action is produced. Between the two plates there is something (say the liquid) which causes the action; it is, in fact, the presence of this liquid which calls the chemical affinities into play.

A word must now be introduced which will often occur during the lecture, and it is one which performs an important part in the measurement of electricity of the character which men utilise, *i.e.*, resistance. Indeed, this resistance to the free passage of an electric current is now our chief business. Whilst the size of the plates in these cells is increased, the resistance to the free course of the manifested electricity is not decreased. Thus, for instance, from a square inch of one plate there is a current of electricity meeting or co-operating with that developed from a square inch of the opposite plate. Whatever may be the energy of the chemical affinity upon one square inch, it is met by the energy of the chemical affinity upon the opposite square inch of the other, and that energy has to overcome the resistance of the liquid between them. Now, then, assume that each of these plates is enlarged by the addition of another square inch. This introduces an additional quantity of liquid, and we have to overcome the resistance of this liquid. The difficulty of overcoming the resistance of the intervening liquid is such that, however much we multiply the number of square inches, we also introduce more liquid, and, by so doing, add further electrical resistance. Hence, however large may be the plates, we do not overcome the resistance more easily. That led to the contrivance of thus coupling up in what is called "a series" in the form you see here, that which is familiar under the name of a cell-battery.

It may perhaps make clear what is a difficulty to many minds, if an attempt be made to explain how it is that as

* The Cantor Lectures, delivered before the Society of Arts.

electrical current which passes when cells are coupled-up "in series," that is, one after the other, is more intense than when they are combined as one large single cell.

Supposing these two plates, each 1 square inch in area, were the only two concerned, therefore there would be a certain resistance to be overcome. The chemical affinity of one such combination not only overcomes that resistance, but leaves a surplus of electricity, which surplus is said to run along the outside wire, and may produce what we call a telegraphic dispatch. Now, suppose that, in addition to those two plates, there are two others of the same size and material in a cell behind them. Between these second plates there is also a resistance similar to that between the first two. Those two second plates, however, also produce a surplus. Now, as that surplus passes over, it continues its way through the previous plates and wire, and the consequence is that, when once the resistance of its own cell has been overcome, the surplus electricity can pass through the other cells without any resistance, and, therefore, we are enabled to add the surplus of one cell to the surplus of the next, and so on. Hence, when combined in the form in which they are combined in this battery, we are manifestly enabled to pass along the connecting wire successive equal amounts of electricities, and these, flowing so very closely behind each other, produce an effect upon any resistance similar to that produced upon a slab of marble or of glass by the forcible driving against it of small grains of sand in a continuous stream. These grains penetrate, and, as it were, bore holes even in hardened steel; so these successive electricities are, as it were, continuous, and thereby overcome great resistances. It may, in connection with this, be remarked that, perhaps, in some such way as now described, the mighty energies of affinity may be accomplished by this clashing of millions upon millions of atoms and molecules. This may explain how and why it is that these cells thus arranged "in series" are under certain circumstances more effective than when the same amount of liquid and metallic elements operate as one cell only.

Electricity thus, or by other means at our disposal, is now to be measured. Two things are especially before us now. One to make clear how this measurement is made; the other to endeavour to make clear how the resistance of various bodies, be they wires or liquids, is also measured.

This electricity is measured in a very simple way. All the apparatus is here, but as it would take too long to show experiments in detail, perhaps you will kindly accept a statement of facts instead of a visible reproduction of them. In these cells is being produced a quantity of electricity, which is to be measured, much as sugar is measured by the pound, or liquids by the quart. The way it is measured is either by the chemical decompositions that it can produce, or by the amount of heat it can develop, or by other means, as, for instance, its effect upon the magnet in a given time.

This seems a convenient opportunity for directing attention to a galvanometer, which is arranged upon a plan by which is shown the amount of decomposition effected by the current indicated by the place of a needle on the dial. The gentleman who designed it had in view only a manufacturer's requirements. The measurement effected by such a galvanometer is not of that character with which this lecture is to be concerned, and therefore further reference to this particular one is not requisite.

To consider a mode of measurement we must recur to those elements—mass, space, and time. The apparatus on which my hand now rests consists of a wooden ring, about 10 inches in diameter, having coils of copper wire round it. Within this circular box with a glass top is a small magnetised steel needle. Now, the small steel needle assumes a certain position in consequence of the influence of terrestrial magnetism. Such an influence as this is not unlike a stream of water in a brook upon a short stick, one end of which is tied to a stake by a

string. So long as the stream flows steadily past the stick it is retained in the same position. Let a disturbance take place in the evenly flowing water, and the stick will no longer retain either steadiness or direction. Suppose, now, that this needle is retained in a certain direction by the influence of what we may call the stream of terrestrial electricity flowing through the atmosphere of this room. (That such a stream is so flowing through the atmosphere shall be made apparent presently.) From these four cells of a galvanic battery a current of electricity may be caused to pass along the wire which surrounds this wooden ring. The arrangements are made, and such a current is now passing. What is the consequence? The even flow of that which retained the needle is disturbed, and the needle answers as the stick in the water would have done to the disturbing causes. Clearly the nature and extent of the invisible disturbance may be estimated—indeed measured—by the motions of the visible needle, just as a new position assumed by the stick would measure the disturbing influence on the stream.

The promise to let you have proof that there are currents of electricity passing through the atmosphere of this room may now be redeemed. Here is a circular wooden ring, with wire round it as before. You may notice that it can be turned as a looking-glass in its frame. The ends of the wire coiled round it are now connected with the wires of the galvanometer, the mirror of which reflects that speck of light on the screen. The looking-glass mounted ring is placed in reference to the (so-called) current of electricity always passing through the atmosphere, that were there a glass in the frame the current would beat upon that glass. If the frame be turned one-fourth round, then the current will pass parallel to the face of the frame. Or thus:—If the frame of the wire-enclosed ring be placed parallel to the direction of this magnetised needle, then the current of electricity through the atmosphere of this room is passing parallel to the ring. To move it, therefore, from this position to one at right angles to it, it is clear that the circumferential wire must, as it were, cut the stream of electricity, if there be one. Now, so cutting it, there will be a disturbance in the electrical condition of the wire, which may be manifested by a motion of that speck of light. Observe now, that every motion of the frame causes a motion in the needle of that galvanometer, which is placed on a stand far removed from the table on which the motion of the frame takes place.

The two experiments now made may satisfy you:—

(1). That there is what, for want of another name, we may call a current of electricity passing through the air; (2) that disturbance of the uniform quiet flow of this current may be caused; (3) that this needle is sensitive to such a disturbance; and (4) you will perhaps accept my word for that which time alone prevents being illustrated, viz., that the amount of this disturbance may be measured by the needle—that is to say, the greater the disturbance the further will the needle be moved from its original position.

It will be obvious to all that the amount of motion in the needle for any given disturbance will depend upon its sensitiveness. Hence, two needles may or may not move equally from the same cause. A mode of measurement, therefore, which depends upon an artisan's capability to make either unit jars or needles equally sensitive cannot be one to be much relied upon. There is, however, a relationship between the motion of the needle and a totally different mode of absolute measurement of the quantity of electricity that may pass in a unit of time, which solves the difficulty now expressed.

The usual apparatus for the decomposition of water by an electrical current is standing here. It is in consequence of completing the wire circuit from this combination of four cells that decomposition takes place. The bubbles are rising regularly and rapidly. Patient

and watchful experimenters have established this, viz., the amount of water thus separated into its constituent elements of oxygen and hydrogen is always in exact proportion to the quantity of electricity that passes. If, then, it were convenient to be thus always decomposing water, a measure might be had. Thanks, however, to the mathematician, we have a much more simple mode of gaining this knowledge.

Suppose one end of the wire from these four cells is connected with the decomposing apparatus—this apparatus connected to the ring already explained—then from the ring to the other end wire of the cells. With such an arrangement observations can be made both on the decomposing apparatus and the deflections of the needle, when each is under the influence of the same current. If the quantity of electricity in the circuit varies, the amount of gas produced and the position of the needle vary also. These have been so frequently observed, that by looking at the needle the mathematician could always tell the amount of gas obtained; in fact, he could lay down a very simple rule for guidance. The application of this rule enables a person at all times to state what quantity of electricity is passing, even though he look to the needle only.

An arithmetical illustration may make this clear. Suppose that in one minute these gases, which may be seen coursing up the tube, filled a space in the tube marked 10 cubic inches—observe where the needle pointed. Let us assume that it is pointing to 45°. Suppose on another and future occasion the needle is observed to point to 60°, now, either from memory or from tables, we find that the tangent of 60° is entered as 1.73. Then, if ten be multiplied by 1.73, the result would be that 17.3 cubic inches of gases might be evolved. As there are in chemistry laws connecting the composition of bodies, such a result as this would enable a manufacturer to know how much silver, for example, this current of electricity would cause to be deposited in any fixed space of time. Thus may be measured the quantity of electricity passing in a unit of time.

But the deposition of gold and silver or other metals is not the only utilisation of electricity, and as other results of a very different kind are obtained from this "imponderable," it is time to turn to illustrations of another form.

(To be continued.)

CORRESPONDENCE.

PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—Your able article on "Public Analysts" in the CHEMICAL NEWS of last week expresses the feelings and opinion of many aggrieved chemists.

It is mortifying to perceive persons of no more knowledge of chemistry than is acquired in the usual course of hospital instruction step into those appointments intended by the legislature and the nation to be filled by men whose training and education have fitted them for the profession of analytical chemist. It is not possible that a medical man, who, previous to his election to the post of analyst by a body of small grocers and dairymen, has perhaps never performed a quantitative analysis in his life, can, after three months study even in a special laboratory, have obtained sufficient experience in analysis to fit him for the responsible position he is elected to.

One might explain the fact of the analyses now performed by these gentlemen not showing many cases of serious error on the hypothesis that, when a mistake through want of skill or manipulation is imminent, the statement of analysis is so arranged as to screen the analyst himself from any possible imputation.

But really, Sir, the number of analyses that have been

performed by these medical analysts since the A& came into force are so few and far between, that the blunders committed must necessarily be likewise small and few in number.

Altogether, the Adulteration A& does not seem to be carried out in the spirit it demands. In many places there are no analysts at all, and the electing bodies do not even intend that there should be any. In Lancashire there are, I believe, only four appointments filled, viz., those of Liverpool, Manchester, Salford, and Bolton, while all the numerous other towns and thickly populated districts are entirely without analytical supervision. It is a pity that such a good movement should be so imperfectly followed up.—I am, &c.,

RIA.

Nov. 2, 1873.

PUBLIC ANALYSTS FOR STAFFORDSHIRE.

To the Editor of the Chemical News.

SIR,—Under the head of "Miscellaneous," in your impression of last week, it is stated that Mr. W. L. Scott has been appointed Analyst under the Adulteration A& for Derbyshire and Staffordshire. This requires slight correction in case of the latter county; for, although Mr. Scott is Public Analyst for North Staffordshire, I hold the appointment for the Southern Division, as well as for this borough.—I am, &c.,

E. W. T. JONES.

Borough Analyst's Laboratory,
10, Victoria Street, Wolverhampton.
November 1, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, September 29, 1873.

Action of Gases in Coagulation of Albumen.—MM. Mathieu and Urbain.—When the gases dissolved in serum of blood are completely extracted, there is obtained an albuminous liquid which does not coagulate even at a temperature of 100°. This experiment, performed with egg albumen, formed the starting-point of the present research. The mercury pneumatic machine extracts not only the gases from albumen, but the volatile salts. The two cases are considered separately. The authors show—(1) That carbonic acid is the agent of coagulation of albumen by heat; and (2) that albumen, deprived of its volatile salts, is transformed into globulin.

New Treatment of Cholera, and probably of Yellow Fever, by Phenic Acid and Phenate of Ammonia Subcutaneously Injected.—M. Declat.

Extent of Variations of the Solar Diameter.—M. Respighi.—In this preliminary note the author replies to P. Secchi's assertion of his instrument being faulty on account of the weak dispersion of the prisms, causing undulations and oscillations, more or less marked, at the edge of the spectral image of the sun: whereas in P. Secchi's instrument, with highly dispersive prisms, the edge is still and distinct.

Action of the Respiratory Apparatus after opening of the Thoracic Wall.—MM. Carlet and Strauss.—The

authors experimented on a man having a fistulous opening into his pleura. They find—(1) That the lung of the injured side follows, to a certain extent, the movements of the thoracic cage, expanding during inspiration, and contracting during expiration, thus behaving similarly to the sound lung. (2) During closure of the thoracic opening there is intensification of the preceding phenomena; hence, after the operation for empyema, the wound should be kept closed as hermetically as possible by means of an apparatus of caoutchouc. (3) The repeated efforts after the operation form a sort of pulmonary gymnastics, which the physician should utilise.

Researches Relative to the Action of Heat on Carbonaceous Virus.—M. Davaine.

Influence of Sulphates in Production of Goitre, apropos of an Epidemic of Goitre observed in the Barracks at St. Etienne.—M. Bergeret.—The author holds the theory just indicated; but in the case of these barracks, in which there are at present some 250 goitrous soldiers, the cause (sulphate of copper) is not traceable to the water, which is extremely pure, and gives no precipitate with salts of baryta or of silver or with ammonia: photographers use it in place of distilled water. The explanation given is as follows:—For an adult to be in perfect health the anatomical tissues and organs must receive assimilable principles in equal weight with those which they incessantly destroy to maintain animal heat, and produce the mechanical work required of them. If the receipt is not equal to the expenditure there is consumption anæmia. Something of this kind occurs in the goitrous soldiers of the barracks; they have excessive work, and have not a diet proportioned to the force expended. Again, it is known that when a muscle is exerted continuously, or when it is subjected to a continuous electric current it becomes acid (consuming its own substance) the acids produced being sulphuric and phosphoric, at the expense of the sulphur and phosphorus contained in the albumenoid matters. Under such conditions a man has in circulation in his blood an abnormal quantity of sulphates, exactly as if he drank water containing these substances. From an analysis of the urine of the goitrous soldiers at different stages of the disease, M. Bergeret finds that the maximum quantities of sulphates is during the full progress of it; it is three or four times that in the normal state. The urine at the commencement ranks next, and then that of the convalescent stage.

Remarks by Baron Larrey on the Communication Relating to Acute Thyreoiditis, called Epidemic Gôitre, among Young Soldiers.—The Baron has frequently found young soldiers suffer from an enlargement of the thyroid gland and neighbouring tissues owing to pressure of the shirt button, coat collar, and clasp of the chapote; a purely mechanical cause. On replacing the collar with a cravat the glandular swelling disappeared. He is unwilling to accept the term *epidemic goitre* for an affection at once simple and easily remedied, and which he calls *thyreoiditis*; and he suggests the possibility of the mechanical cause acting in the St. Etienne case.

October 6, 1873.

Notice of a New Derivative of Propyl. (Continuation.)—M. A. Cahours.—The author has prepared and examined oxalo-propylic ether, $C_{12}H_{14}O_8$. It boils between 209° and 211° . If alcoholic ammonia is allowed to act upon it a crystalline substance is obtained of the formula $C_4H_2NO_5C_6H_7O$. Carbonate of propyl, a colourless limpid liquid, boils between 156° and 160° . Its composition is $C_{14}H_{14}O_6$. Salicylate of propyl, $C_{20}H_{12}O_6$, boils between 238° and 240° . It is sparingly soluble in water, and has a hot aromatic taste. With chlorine and bromine it gives rise to crystalline products of substitution. Phenate of propyl, $C_{18}H_{12}O_2$, is a colourless mobile liquid of a pleasant odour, boiling between 190° and 191° . It is energetically attacked by bromine and nitric acid, and

yields with sulphuric acid a copulated acid. Nitrite of propyl, $C_6H_7NO_4$, boils between 43° and 46° . It is a homologue of nitrous ether, and isomeric with nitropropane.

Elastic Yellow Tissue, and on Proximate Organic Analysis.—M. Chevreul.—The author maintains that Bichat first recognised the yellow elastic coating of the arteries as a distinct tissue, and insists on the importance of seeking out the proximate principles contained in living beings.

Sanitation of Marsh Lands by Means of Eucalyptus Globules.—M. Gimbert.—The author maintains that this tree, a native of Australia, has the power when planted in marshy lands of improving their sanitary conditions, as has been proved in Algeria and Cuba. It drains the swamps, and at the same time gives off antiseptic vapours.

Condensation of Gases and Liquids by Wood Charcoal; Thermic Phenomena Arising on Contact of the Liquids, and the Charcoal Liquefaction of the Condensed Gases.—M. Melsens.—This paper has been already noticed.

Production of Certain Crystalline Borates in the Dry Way.—M. A. Ditte.—The author makes use of a mixture of equal equivalents of alkaline chlorides in which he introduces the amorphous borates or the elements of the salts which he wishes to obtain. The bottom of the crucible being heated to redness a part of the borate dissolves in the fused mass, and crystallises in the upper and cooler portions. In this manner the borates of lime BoO_3CaO ; $3CaO,2BoO_3$; and $2CaO,3BoO_3$; and the borates of strontia, $SrO,2BoO_3$; $2SrO,3BoO_3$; SrO,BoO_3 ; and $3SrO,2BoO_3$.

Researches on Tribromacetic Acid.—M. H. Gal.—This acid consists of—

Carbon	8.70
Hydrogen	0.33
Bromine	87.50
Oxygen	3.47

100.00

It is easily etherised. In presence of alkalis and under the action of heat it is decomposed, giving rise to bromoform and the carbonate of the base employed. This acid is very energetic, its salts crystallise readily; that of baryta forming long needles, and that of copper bulky prisms, apparently isomorphous with the acetate.

Claim to Priority as regards the Action of Ammoniacal Gas on the Nitrate of Ammonia.—Dr. E. Divers.—With reference to the memoir of M. F. M. Raoult on this subject (*Comptes Rendus*, May 12, 1873). Dr. E. Divers shows that his paper on the same reaction was presented to the Royal Society October 29, 1872, read January 9, 1873, and published in its *Proceedings*.

Note on Means for Maintaining in a Given Place a Temperature Nearly Constant, and for Moderating in Summer the Temperature of Dwelling Houses.—Gen. Morin.—The principle of the author's method is to renew the air regularly through the introduction by moderated aspiration of fresh air at constant temperature. It is known that at a depth of about 24 metres the internal temperature of the ground is constant. A supply of air is drawn from pits at this depth, or a less depth may suffice. The general dispositions are as follows:—The principal room, in which the temperature is to be kept constant, is preceded by another of nearly the same capacity (or only a small antechamber), which acts as a sort of dam for the entering air. This room should have walls, ceiling, and floor pretty thick. The floor and walls rest upon vaults; the walls are surrounded at a short distance by an isolating *enceinte* of the same form, communicating with the vaults and the bottom of the aëration pits. Orifices made near the top of the ceiling of the room and that of the *enceinte* are in direct but distinct communication with draw tubes (*tuyaux d'appel*) in which are burners kept lighted under

constant pressure; their number varied according to the season. The air to be introduced into the principal room, into the subterranean vaults, and into the envelope, is taken from near the bottom of the pits by a special pipe of suitable size. The added building may be in a street, and may be lighted by double windows on the north side: the interval in the windows being in free communication with the isolating envelope. The author shows, from Newton's law, that the volume of air to be introduced is greater the nearer the temperature to be maintained inside approaches that of the air introduced, and the more extensive the cooling surface (it would become infinite if the interior temperature were equal to that of the introduced air). Further, that, other things equal, this volume will be proportional to the value it is judged convenient to assign to the fraction—

$$\frac{T - T'}{T' - t}$$

where T is the temperature external to the added building or its envelope, T' the internal temperature, and t the temperature of air to be introduced into it. The question is simplified wherever the fraction is supposed = 1. (Some numerical examples are given.) In places where instruments of precision are kept the temperature should be a little above that of the air introduced; otherwise the entering air in cooling deposits on the walls and apparatus a portion of its vapour. The foregoing arrangement is valuable for various applications, as places of meeting, places for keeping food, &c.

Report on Memoir by M. Mannheim on the Trajectory Surface at the Points of a Figure of Invariable Form, the Displacement of which is Subject to Four Conditions.

Studies on Phylloxera.—M. Max Cornu.—The author asserts the identity of the insect attacking the roots with that attacking the leaves, but it seems less attracted to the leaves.

Effects of Sulphide of Carbon used to Destroy Phylloxera on the Vine Itself.—M. Lecoq de Boisbaudran.—The leaves of vines thus treated have withered, though remaining attached to the branches. The remedy seems effective against phylloxera but, besides injuring the vines, is too expensive to be used.

Size and Variations of the Sun's Diameter.—(Second note by M. Respighi).—P. Secchi has stated that the duration of passage of the solar diameter, measured by mono-chromatic images obtained in the spectroscopic telescope with the direct-vision prism before the slit, was less than the duration given in the Greenwich Nautical Almanack by about 0.6 s., whence he infers that the diameter of the mono-chromatic image of the sun is about 8 seconds less than the diameter of the image with compound light, obtained by the simple telescope with coloured glass. M. Respighi is unwilling to admit this difference. He suggests possible causes of error; imperfect rectification and instability of instrument, influence of atmospheric refraction, but more especially the influence of variations of temperature of the prism. These sensibly displace the spectral lines. The results are constant P. Secchi says; but it is replied, that during each passage of the solar image the temperature of the prism could not continue constant, and its variations would be reproduced periodically in successive passages (independently of the absolute temperature). It is precisely these periodic variations which might displace the solar image by a quantity nearly constant in all the successive passages. (This influence is much less sensible in the author's own instrument, in which the aperture is reduced by a diaphragm, and the prism has little absorption.) Other possible causes of error are the undulation or agitation of the sun's border, and the personal error in observation of the two contacts. Some of the causes mentioned are avoided by using the objective prism. The author's observations by both methods gave results differing very

little from those in the Nautical Almanack (not more than + or - 0.12 sec.)

Theory of Earth Pressure.—M. Curie.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., No. 6, October 9, 1873.

Absorption of Gases by Charcoal, and their Spontaneous Liquefaction.—M. Melsens.—This chemist has obtained wood charcoal absolutely pure, and possessed of such high absorptive power that it can concentrate in its pores its own weight of gas. When charcoal thus saturated with any of the more readily liquefiable gases, such as cyanogen or chlorine, is placed in a glass tube fitted with a neck bent at right angles and closed at one end, and heated to 100° by a current of steam, the gas escapes, and compressing itself in the closed end of the tube passes at once to the liquid state.

New Generator of Electricity.—M. Clamond has constructed a new thermo-electric apparatus, which is ready to give a powerful and constant current whenever the furnace is lighted, and from which important industrial results are expected.

No. 7, October 16, 1873.

Cultivation by Means of Dynamite.—It is proposed, instead of ploughing or digging the ground, to bore holes, fill them with dynamite, and explode them!

No. 8, October 23, 1873.

This number contains no original chemical matter.

No. 9, October 30, 1873.

International Patent Law.—The Congress of Vienna has unanimously passed resolutions in favour of this desirable reform.

Phosphates of Quercy, of Lot, &c.—These phosphates appear to furnish phosphoric acid to the soil if spread on the land in their natural state, without any other treatment except grinding to powder. They appear to contain a proportion of bibasic phosphate, which accounts for their solubility and efficacy.

Method of Determining Sugar by Means of a Salt of Iron.—M. E. Riffard.—Perchloride of iron solution, prepared by dissolving in pure water the crystalline perchloride of iron, requires to 100 milligrams of iron 2.587 grms. of sugar to remain unprecipitated in presence of ammonia. 25.87 grms. of the sugar to be tested are dissolved, a few drops of oxalate of ammonia added to throw down any lime, filtered, and the solution made up to 250 c.c. Of this 25 c.c. are taken, and according to the number n of hundredths of pure sugar contained in the sample n hundredths of iron may be added, and will remain dissolved. In two determinations different results are obtained, viz., with n milligrams of iron, a limpid solution; with $n+1$, a precipitate; n being the percentage of sugar in the sample. With sugars of unknown origin the sample is previously shaken up in the cold with alcohol at 95 per cent, and filtered to remove inverted sugar, which has a stronger action on iron than crystallisable sugar. The author states that the results obtained by this method agree with those furnished by the saccharimeter.

Treatment of Resin Oils.—When heat is applied to the retorts a light oil, crude pinoline, passes over at first, and then ceases. The receivers are changed, and the fire augmented, when the heavy oils pass over, and colophonium is left in the retorts. The heavy oils are of a deep violet colour. They are boiled for a day with water, and a part of the matter which passes off with the steam is collected. The next day the water is drawn off, and the residue saponified with caustic soda at 36° B. The almost solid product is then heated anew till no more oil distils over. The oil which has been distilled (single rectified) is submitted again to the same treatment, and that which finally passes into the receiver is called double

rectified. It is used for adulterating fish oils. Crude pinoline contains acetic acid, from which acetate of lime may be prepared by neutralising the crude product of distillation with chalk, and re-distilling the oily liquid.

Use of Slags.—At Osnabruck slags are granulated by being allowed to flow at high temperatures into water. Thus divided it can be used as ballast for railways. If much alumina is present the slags can be used in the manufacture of alum.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 35, 1873.

Manufacture of Iodide of Potassium from the Mother-Liquors of Kelp or Crude Soda.—This process consists in transforming into iodates the alkaline iodides contained in kelp lyes; then in precipitating the iodic acid with a soluble salt of baryta, heating the precipitate with a solution of sulphate of potassa, which yields a solution of iodide of potassium, evaporating this to dryness, and finally fusing the residue, and allowing the solution of the iodide of potassium thus obtained to crystallise. The conversion of the iodides of the mother liquors into iodates may be effected by one of the methods indicated below; but it is important to precipitate entirely or in great part the sulphuric acid contained in these waters by means of chloride of barium. At the same time a little silicic acid and other impurities are eliminated, and it becomes more easy to treat the product obtained by the iodate of baryta. After having collected this precipitate the mother liquor is evaporated to dryness to destroy the organic matters present, and the residue is fused. The liquid obtained from the solution of the melted mass after being freed from insoluble matters is rendered alkaline by the addition of a caustic or carbonated alkali to such an extent that there may be 5 atoms of caustic alkali or 10 of carbonate for each atom of iodide. This addition of alkali is unnecessary if the fourth of the following methods is to be employed. (1) A current of chlorine is passed through the liquid until the iodide is transformed into iodate, but no longer. (2) A solution of an alkaline permanganate is added to the liquid until a very slight but permanent rose-coloured tint is produced. The precipitate of manganese is filtered off, and re-converted into permanganate by fusion with soda or soda and saltpetre. (3) An electric current is passed through the liquid. (4) An atom of an alkaline chromate is added for every atom of iodide present. The whole is evaporated to dryness, cautiously heated without raising the temperature to redness until the iodide is converted into iodate. After the iodic acid is removed from the mother-liquor the bromide which may remain in solution is transformed into bromate by the first or fourth method above-mentioned.

No. 36, 1873.

This number contains a notice of a machine for roasting coffee, starch, barley, &c.; the effervescing beverages manufactured by Nitot et Cie.; and of the method of rendering cloth water- and fire-proof carried out by Dujardin.

No. 37, 1873.

This number is totally free from chemical matter, whether scientific or industrial.

Revue Scientifique de la France et de l'Etranger,
Octobre 11, 1873.

M. Zinin shows that desoxybenzoin dissolved in alcohol with caustic potassa absorbs oxygen from the air, forming benzoic acid and a very complex body, benzamaron; which, on prolonged ebullition with caustic potassa, reforms desoxybenzoin and amarinic acid.

Fritsche finds that tin may be rendered crystalline and brittle by exposure to intense cold.

Boutlerow has made experiments on isobutylene to verify the hypothesis of a double series of atoms of carbon in the non-saturated carbides of hydrogen. Isobutylene yielded instead of crotonylene an isocrotylic ether.

Mendeleew has determined the calorific capacity of cerium.

Boradine has studied a monatomic alcohol containing 10 atoms of carbon obtained by the action of sodium on valeraldehyd.

Lazarenko having found that benzoyl-anilid does not yield directly nitro-derivatives has prepared them by causing nitro-benzoic aldehyd to act upon anilin, and benzoic aldehyd and nitro-benzoic anilin upon nitranilin.

Struve concludes that all combustion generates ozone, peroxide of hydrogen, and nitrate of ammonia.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the treatment of stable manure and for obtaining useful products therefrom. Arthur McDougall, of the firm of McDougall, Bros., manufacturing chemists, Manchester and London. February 13, 1873.—No. 542. This invention consists in treating stable manure or litter, which has hitherto been used only as a fertilising agent, in such a manner as to render it available for use in the manufacture of paper-pulp, and consists in thoroughly washing such manure or litter with water by any suitable or well-known mechanical contrivance, with a view to the removal of the fecal matter therefrom. The cleansed straw thus obtained may either be treated by any suitable or well-known process for the manufacture of the same into pulp for the making of paper and similar products, or it may be dried and again used as bedding for horses and cattle generally.

Improvements in electric telegraphs. Henry Highton, M.A., Putney, Surrey. February 13, 1873.—No. 545. This Provisional Specification describes special arrangements by which the gold-leaf instrument is applied advantageously to work long lines, especially where the insulation is defective.

Improvements in the manufacture of iron and steel. Jacob Geoghagan Willans, 9, Saint Stephen's Crescent, Bayswater, Middlesex. February 14, 1873.—No. 547. Ore in a divided state is employed together with materials to prevent its falling through the interstices of the fuel. Apparatus is also described for charging the furnace. Improvements on the "Uchatius" process are also described, and granulated metal is produced for the manufacture of steel and malleable castings.

An improved composition for removing and preventing incrustation in boilers. David Hutchison, Mile End, and William George Bridges, Stepney, Middlesex. February 14, 1873.—No. 551. The features of novelty of this invention consist in combining together catechu, chlorine, linseed, sodium, nitre, sulphate of potash, alum, calcium, and ammonia, in certain proportions.

Improvements in apparatus and in the materials and appliances employed for the filtration of water, sewage, and other fluids, whereby manure and other valuable products are separated, precipitated, and obtained therefrom. Francis Henry Atkins, engineer, 62, Fleet Street, London. February 14, 1873.—No. 556. One part of this invention has for its object improved arrangements of apparatus and mechanism for the filtration of water, sewage, and other fluids, being specially adapted for the separation of the grosser impurities from water for manufacturing and other purposes, or for filtering the effluent water of sewage, the polluted water from paper or other manufacturing works to prevent the pollution of rivers, or for other purposes. The invention also relates to the preparation and application of coke in solidified blocks or slabs, for the filtration of water, sewage, or other fluids. The filtering materials in the form of blocks are secured in open removable frames or slides. The frames with the filtering blocks or slabs are then placed and fixed in position across a water-course, tank, passage, or channel, through which the water, sewage, or other fluid to be filtered is arranged to flow. Part of the series of frames may contain sponge, felt, or other filtering materials. When the filtering slabs are coated with the impurities, they are removed and allowed to dry, and are cleansed by scraping, the scrapings being converted into manure. According to another of these improvements, the grosser impurities are withdrawn from water, sewage, or other fluids by means of endless bands of wire-gauze, hair-cloth, canvas, sponge, or other suitable materials mounted upon rollers, and arranged so as to revolve in a tank or passage, through which the fluid to be filtered flows. Another part of these improvements has for its object the application of galvanic, magnetic, or electrical action to filtering apparatus, reservoirs, or tanks, for the purpose of precipitating organic and inorganic matters or impurities held in suspension or solution in the water or other liquids.

Improvements in the deodorisation of excreta, and in the manufacture of manures therefrom. Major-General Henry Young Darracont Scott, C.B., Ealing, Middlesex. February 15, 1873.—No. 570. The object of this invention is the prevention of nuisance in dealing with night-soil and urinous liquids, and the fixation of their fertilising elements so as to render them valuable marketable commodities.

Improved methods for purifying gutta-serena. Thomas Cattell, M.D., Clarendon House, 25, Clarendon Square, Middlesex. Fe-

bruary 17, 1873.—No. 587. By this invention crude gutta-percha is deprived of its impurities by treating it by—Process No. 1. The solutions of gutta-percha, made according to Specification No. 446, 1859, are filtered or strained, and the gutta-percha recovered by means of alcohols, vapour of alcohols, or steam. Process No. 2. Crude gutta-percha is softened by the action of solvents, hot water, or steam, and mechanically strained, and the solvents afterwards removed and recovered by means of steam. Process No. 3. Crude gutta-percha is softened by a mixture of the usual solvents of gutta-percha with alcohols, and mechanically strained, and any solvent adhering to the gutta-percha drawn off by steam, and collected. Process No. 4. Gutta-percha, obtained by what is termed in the said Specification, No. 449, "the process of congelation," is broken up and passed into a chamber, where it meets either the vapour of alcohols or steam, and the solvents of the gutta-percha, or the alcohols used are collected.

Improvements in spicing and preparing malt or distilled vinegar, rendering the same better suited for pickling purposes. Annetta Jane Honor Hutchings, 2 and 3, Quay Head, Bristol. February 17, 1873.—No. 588. The inventor takes malt or distilled vinegar, chilis, cloves, ginger, pimento, mace, and nutmeg, all or some, and (1st) grinds and commingles together the spices, and (2nd) places the ground spice in an earthen or other vessel with perforations in the bottom, which vessel is placed in another earthen or other vessel. Both vessels are placed in a boiler, the vinegar being poured into the inner vessel upon the spices, and the contents of the boiler being kept simmering for a sufficient time, the strength of the spices is drawn out into the second vessel, and, upon being filtered, is fit for bottling.

NOTES AND QUERIES.

Distillation and Purification of Glycerin.—Can any of your readers give, or refer the enquirer to, information on the above?

Maximum and Minimum Thermometers.—Mr. H. Smith, in his "Chemistry of Sulphuric Acid Manufacture," describing his experiments on temperature, says that he used "ordinary maximum and minimum thermometers" fixed on glass; I should feel much obliged if he would give me a further description of the sort he used, and if he could say where such are to be procured.—A MANUFACTURER.

Malleable Cast-Iron.—I should be thankful if you, or any of your scientific correspondents, would, through the medium of your paper, kindly give me a little information respecting malleable iron castings. (1). Are the so-called castings malleable? (2). Is malleable cast-iron chemically different to common cast-iron, and what is the difference? (3). How is malleability produced in cast-iron? By oxidation of the carbon, or some other chemical process? By a mixture of wrought-iron, or by annealing?—RICHMOND BAKER, Cert. Teacher of Science, The Gouger Street Academy, Adelaide, S.A., Sept. 10, 1873.

Iron Wire in Claret.—A small fragment of wire having been accidentally left in a bottle of claret, communicating a most abominable taste to it, I dropped in a scrap of silver-foil and corked it up again, removing the remnant of iron wire. In a few days I tasted the wine again, and found that, though nasty, the worst part of the taste, that of hydrogen sulphide, had disappeared. Had the sulphur been present as impurity in the iron? It has struck me that perhaps small aquarium tanks might be saved if, at suspected spots where minute fixed organisms are perishing, scraps of silver-foil were placed with the tongs; at all events they would remove the H_2S evolved. May I ask if this has been tried, or if, in the opinion of chemists and naturalists, it is likely to be of use?—MARSHALL HALL.

A New Method for the Preparation of Chromic Acid.—The following method is based upon the decomposition of barium chromate by nitric acid, with the separation of the barium nitrate thus formed, by means of sulphuric acid. Precipitated barium chromate is added to boiling nitric acid (diluted with an equal bulk of water) till completely saturated; the whole is then allowed to cool, when the greater quantity of the barium nitrate crystallises out. To the mother-liquor a sufficiency of sulphuric acid is added, to precipitate the remainder of the barium; the barium sulphate settles readily to the bottom of the vessel. The supernatant liquor, containing chromic and nitric acids, is drawn off and evaporated to dryness on a water-bath, when all the nitric acid is expelled, leaving a residue of nearly pure chromic acid, which may be purified by crystallisation. By this method, nearly the theoretical quantity can be obtained from potassium chromate.—J. McLELLAN, Shawfield Chemical Works, Glasgow.

Detection of Petroleum Spirit in Coal-Naphtha.—(Reply to E. J. D.).—First, test the specific gravity of the naphtha; should this indicate, say, 0.86 or thereabouts, there are some grounds for suspicion as to presence of petroleum spirit. Next, place about 250 c.c. of the suspected naphtha in a flask fitted with Liebig's condenser and thermometer, and distil off all coming over below 115° to 120° C. Take this portion boiling below 120° C., and place in a fresh flask, and distil again, collecting apart all coming over below 85° to 90° C. This is tested as to its odour and specific gravity, and, if petroleum spirit has been used, the former is usually sufficiently unmistakeable, but is further confirmed by an examination as to the latter, the extreme lowness of which will decide the point. Scotch naphthas have usually a somewhat lower specific gravity than English; in fact, they are frequently met with as low as 0.86. To decide if genuine, i.e., free from spirit, make the above-mentioned examination in the manner described, and, if the lowest boiling portion extracted thus from the bulk possesses, after the second distillation and extraction, a specific gravity not differing very materially from that of the bulk of the original naphtha, the sample may be considered genuine as regards light petroleum spirit.—WATSON SMITH, F.C.S.

Notes on the Utilisation of Sewage.—(From the "Report of the Main Drainage Committee for 1864," vol. 487).

1886. (Mr. Bowing). Mr. Hughes, in his book on waterworks, says, p. 291, that the cost of covered reservoirs varies from 30s. to £3 per thousand gallons of capacity, and that the cheapest reservoir which was built was at Wolverhampton. That reservoir contains 1,500,000 gallons, and the cost, exclusive of land, is said to have been £200. He says that a reservoir to contain 2,000,000 gallons would cost £4161, so that it appears that a reservoir costs about £2 for every 1000 gallons.

1900. (To Mr. Ellis). With regard to quantity, is there not among agriculturists a system of high farming and the contrary?—Yes.

1901. And does not that consist, as in Mr. Mechi's case, of putting on very pure land a very large quantity of very rich manure?—You can put a large quantity of solid manure, not of liquid manure, because the liquid manure will run away.

1902. Then your remark applies that there is a limit to liquid manure, but not to solid, is that so?—If you put a larger quantity of liquid manure on the earth than the earth can deal with, it runs to loss. Professor Way's evidence proves that.

2032. (To Mr. Ellis). But if I tell you that I apply sewage to land in frosty weather, and that I have seen it a foot in thickness in ice, and that when the thaw came it melted gradually on to the land and became absorbed, would it alter your opinion?—That would be the case, no doubt; but during the continuance of the frost, it would not be absorbed. There would be nothing to prevent the farmers from applying it at all times, but I assume that they would not do so.

2033. Of course there would be no annoyance from the sewage being in a frozen state?—Of course not.

2041. (To Mr. Ellis). Have you made any calculation of the height?—Yes, if we had to lift the sewage on the north side to 460 feet, that would cost us 0.267,121d., or 4d. 0.017,121 for each ton, or a little over a farthing a ton.

2042. Does that include the cost of the sewage as well as the cost of the carriage?—That would be the cost of pumping only, and lifting it to a height of 460 feet; and that, I believe, is excessive.

2051. (To the same). The evidence of Professor Way proves that there is a limit to the power of the earth to receive manure, and that that limit is very soon reached; therefore, when you put sewage in the great quantity that Mr. Lawes does upon the earth, you must run it away to loss because the earth cannot deal with it.

2052. What amount of sewage per acre per annum did he apply?—On one part of the land 3000 tons, on another part 6000 tons, and on another part 9000 tons per acre.

2053. Do you know what amount Mr. Mechi applies to land with advantage?—I think it is very small; it is 45 tons, or something of that kind.

2069. (To Mr. Ellis). Would you be astonished to hear that a large proprietor has erected works, at very great cost, to be used in a certain district, and that all he required was that the occupiers of the ground should pay for the pumping?—I should be astonished if no explanation were offered.

2090. Those works were erected by the Duke of Northumberland, and then the inhabitants and occupiers of the land in the district refused to pay for the pumping.

2151. (To Mr. West). Have you a detailed estimate there in your hand?—Yes; 200 feet may be pumped at one lift, or you may divide the 300 feet or 400 feet into two lifts. Cornish pumping-engines, including boilers, erected complete, but exclusive of pumps and buildings, will cost £35 per actual horse-power. I cannot estimate the cost of buildings, not knowing the cost of foundations, &c. When in duplicate, they will cost £30 per actual horse-power. For all heights less than 30 feet, the single-acting drawing-pump would be used, and above this height the plunger forcing-pump. The valves should be on the principle of Harvey and West's double beat valves. The cost of lifting 1000 tons 50 feet high will be 2s. 4d., and for every 50 feet 2s. 4d. must be added; therefore to lift this quantity 100 feet will cost 4s. 8d., 200 feet, 9s. 4d.; 300 feet, 14s.; and 500 feet, 23s. 4d. The above includes coal, labour, oil, tallow, and hemp. The cost of lifting one ton is very little; 4½ tons can be lifted 500 feet high for one penny. I would recommend a brass sieve, made in the form of a basket, to be placed at the bottom of the well, through which all the fluid should pass before arriving at the entrance of the suction-pipe; the sieve to be so mechanically arranged for hauling to the surface for clearing.

Now Ready, Price 5s.

Milk-Analysis.—A Practical Treatise on the Examination of Milk (including Cream, Butter, and Cheese). By J. ALFRED WANKLYN, M.R.C.S., Corresponding Member of the Royal Bavarian Academy of Sciences, Public Analyst for Bucks.

London: TRUBNER and CO., Ludgate Hill.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

Two Courses of Lectures on Geological MINERALOGY will be given at KING'S COLLEGE, LONDON, by Professor TENNANT, to which the public are admitted on paying the College fees. One Course is given on Wednesdays and Friday mornings, from 9 to 10 o'clock, commencing Wednesday, October 8th, and terminating at Easter, 1874. The other Course is given on Thursday evenings, from 8 to 9, commencing October 9th. The Lectures are illustrated by a very extensive collection of specimens.

Practical Instruction in Mineralogy and Geology is given by Prof. TENNANT, F.G.S., at his residence, 149, Strand, W.C.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 729.

MEMORANDUM ON THE PURIFICATION OF DRINKING-WATER, WITH SPECIAL REFERENCE TO THAT WHICH IS LIKELY TO BE MET WITH ON THE GOLD COAST.

By WILLIAM CROOKES, F.R.S., &c.

THE following memorandum has been drawn up at the request of Sir William Muir, of the Army Medical Department:—

In the absence of any specific information as to the quality of water likely to be found on the Gold Coast, the following remarks are necessarily somewhat general in character.

Disinfection of water cannot be effected by one substance which removes all the evils at once. There are likely to be many septic bodies in various conditions, and each has to be attacked in a special way.

The danger certainly lies in the organic matter present in the water; but it bears no constant relation to the quantity present. Water may contain a large quantity of peaty organic matter—as much as 4 or 5 grains to the gallon—and be harmless: whilst a very small fraction of this quantity of another kind of organic matter may make it a deadly poison.

Malaria appears to be caused by the decomposition of organised bodies. Soils generally are acid, and the drainage-waters from them are comparatively harmless. But, under conditions which are frequently likely to obtain in a tropical country,—such as great heat, low lying position, damp marshy soil, exuberant and dense vegetation preventing excess of solar rays to the soil—the soil is likely to become more alkaline than the vegetation will bear; putrefactive decomposition will commence, the oxygen in solution in water will be insufficient to restore the balance, and malaria will be the result. In the drainage water from such a tract of country the germs of fatal diseases are almost certain to be present,—to what extent we are ignorant.

That the poison is in the water rather than in the air is well illustrated by a circumstance related by Dr. Woods (CHEMICAL NEWS, vi., 307). Two ships were dispatched simultaneously with troops from Algeria to France, both under similar circumstances, excepting that the supply of water had been drawn in one case from the low marshy lands where ague was prevalent, whilst the other ship had taken water from a locality situate at a greater elevation, and where the disease was unknown. The passengers on board the first transport were quickly seized with remittent fever, whereas no case of illness occurred on board the second vessel.

The means relied upon for destroying or neutralising the poison in bad water are, with the general public, addition of permanganate of potash, and filtration through charcoal.

For general purposes these may be sufficient, but in cases of real difficulty they are likely to be most unsafe, if not positively harmful as leading to a fancied security.

Permanganate of potash exerts extraordinary destructive powers on some kinds of organic matter. Thus the offensive gases of putrefaction are at once deodorised, and many kinds of organic matters, such as oxalic acid, sugar, &c., are almost instantly destroyed. With other substances, however, such as the scent of musk, urea (from urine), the strong smelling valerianic acid, lactic acid (from sour milk), and butyric acid (from rancid butter),

permanganate of potash has little action, and it has not much effect on strychnine, and some other violent poisons.

If we divide the organic matter in water into three classes, viz.:—

- (1). Matter already in a state of putrefaction,
- (2). Matter ready to become putrid,
- (3). Matter which is slow to decompose,

it will be found, *practically*, that the matter in class 1 will be the only organic matter which permanganate of potash will remove. It will destroy this at once, whereas to destroy organic matter of the second class with permanganate of potash will require from fifteen minutes to an hour; and to destroy matter of the third class will require from some hours to some days. Moreover, living matter has considerable resistance to the oxidising power of permanganate of potash; microscopic animalcules will live for upwards of an hour in water tinted with it, and living beings, visible to the naked eye, will live in a much stronger solution.

If a soldier, provided with permanganate of potash, after mixing a little with water waits only a few minutes before drinking it, he will certainly imbibe most of the organic matter of classes 2 and 3; whilst he would have to defer quenching his thirst for about half an hour before the matter of the second class would be destroyed, and for at least a day before matter of the third class would be attacked; and even then he would be by no means safe.

Practically, however, if the soldier used the permanganate at all, he would not be likely to do more than wait for a few minutes.

But the probability is so great as almost to amount to a certainty that the septic matter of the water would reside in the organic matter of classes 2 and 3.

The specific disease-producing particles are doubtless organised germinal matter, or cells, possessing physiological individuality, capable of preserving their activity for a certain time when out of the water in the form of slime, or even dust, able to adhere to material objects, and to be carried from one place to another on the clothing or in currents of air.

To remove these bodies from water, permanganate would be inoperative within the time in which it would be allowed to act. Filtration through charcoal would at first sight appear to be a satisfactory safeguard; but it is not sufficient, for many reasons.

In the first place charcoal acts mechanically as a filter, and should therefore remove solid germs. But these cells are supposed to be so extremely small that it is doubtful whether they would be kept back by merely passing water rapidly through an ordinary filter, whilst if they were kept back they would accumulate only with their tremendous power for evil uninjured, on the upper side of the filter, ready at the first accident to act as the focus of a pestilence.

In the second place a charcoal filter acts as an oxidising purifier for the water which passes through it. The oxygen condensed in its pores destroys organic matter somewhat as permanganate of potash does. To keep charcoal efficacious, however, as an oxidiser, it should be allowed to get dry nearly every day, and should be frequently cleaned. Even at its best it is not likely that it will oxidise organic matter more readily than will permanganate of potash, and hence matters of the second and third class—probably the most dangerous of all—are likely to pass through.

There is another purifying agent which has stood the test of long experience, and which possesses properties which are especially valuable in the present case. I allude to sulphate of alumina. When this salt is added to water containing organic matter of different classes, it passes by that which is so easily oxidised by permanganate of potash, but it attaches itself to organised animal matter—living germs—and converts them into an insoluble substance like leather. It is not quite certain whether this tanning operation destroys

vitality: probably it does; but at all events the precipitate is capable of being filtered with the greatest ease, whilst the addition of sulphate of alumina in no way interferes with the use of the permanganate of potash. If fine clay be used along with the sulphate of alumina the precipitation takes place with great rapidity, and filtration need not be resorted to, but the clear water can be poured off the sediment in the course of a quarter of an hour.

Under the name of A B C compound a mixture of sulphate of alumina, clay, and charcoal has been successfully used by the Native Guano Company for the purification of sewage. At their works I have repeatedly seen the sewage of such places as London, Paris, Hastings, and Leeds, converted in the course of a quarter of an hour from an offensive looking, vile smelling liquid, into water, bright, clear, inodorous, and tasteless, non-putrescible, and so free from injurious matter as to allow delicate fish to live and thrive in it.

With a little necessary modification I consider that a mixture capable of acting thus on town sewage is the most suitable for the purification of water for drinking purposes on the Gold Coast.

I would suggest that the charcoal be omitted, and its place supplied by a permanganate. The ordinary potash salt will do, but if procurable in time I have reasons for believing that permanganate of lime would answer the purpose better.

I have prepared a mixture of—

1 part of permanganate of lime,
10 parts sulphate of alumina,
30 parts fine clay,

and find that when I add this to London sewage in the proportion of 20 to 10,000, the purification is very satisfactory, and the settlement rapid. With foul ditch water a less quantity will do.

The mixture can be filtered, instantly yielding a bright filtrate, or it can be allowed to settle for a quarter of an hour, when the supernatant water can be poured off equally bright.

I am not prepared to say what the price of this mixture would be, but it would probably not be many pence per hundred gallons of water.

PRELIMINARY INVESTIGATION OF THE FLUORESCENT AND ABSORPTIVE SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON Ph.D.,

(Continued from p. 234).

Uranic Oxyfluorides.

THE chemical relations of these salts have been made the subject of a special investigation by one of us, and will be found fully discussed,† but the following brief notes may be useful in this place:—

Uranic oxyfluoride is obtained by dissolving the sesquioxide of uranium in hydrofluoric acid. If the three-fourths oxide be treated with this acid, uranous fluoride also forms as an insoluble green powder, which may be separated by filtration.

Potassio-uranic oxyfluoride, $2(U_2O_2Fl) + 3KH$, is best prepared by adding potassio-fluoride to a solution of uranic nitrate, dissolving the lemon-yellow crystalline precipitate in warm water, and crystallising. The corresponding sodium salt, being very soluble, can be prepared in this manner; it is obtained with difficulty by evaporating a mixture of uranic nitrate and sodic fluoride in a desiccator, has the constitution $2(U_2O_2Fl) + NaFl + 8HO$. The

barium compound forms a crystalline precipitate; the ammonium salt is obtained only as a deliquescent mass.

The following salts have been examined:—

These all fluoresce with various degrees of brightness, and yield very remarkable spectra, having, in the case of two of the double salts especially, a strong similarity to the double oxychlorides in complexity of structure. Their absorption spectra are also marked.

Uranic Oxyfluoride, $(U_2O_2)Fl$.—This salt gives a spectrum which, in the general character of its bands, much resembles the acetate, normal sulphate, &c., or what may be called the normal type. There are, however, in it slight indications of inflections of brightness in the individual bands, which we find strongly developed in the double salts. These indications are, however, too delicate to be correctly represented in the cut, being, in fact, only recognisable when specially looked for. This spectrum is shown at 2 of Fig. 12. The absorption spectrum of this substance is likewise well marked, and is shown in 2 of Fig. 13. When dissolved in water, and acidulated with hydrofluoric acid, this yields an absorption spectrum such as is shown at 3 of Fig. 13. In this the general absorption is strong, and the bands are relatively faint. If no acid is added to the solution of the uranic oxyfluoride, we obtain a spectrum of absorption similar to the above, but with the bands all displaced a little upwards; thus—

Absorption-Bands of Uranic Oxyfluoride in Solution.

Bands.	1.	2.	3.	4.	5.	6.
With acid ..	93°0	103°0	114°0	124°0	136°8	—
Without acid..	95°2	105°0	115°4	125°0	137°6	150°0

The Double Oxyfluorides.

Of these the most brilliantly fluorescent is the potassium salt, and we will therefore describe it in detail, and the others by reference to it. This salt fluoresces pretty strongly, and yields a spectrum in which each band is composite, the stronger or brighter ones showing three elementary stripes, which are recognisable, but by no means so decidedly marked as those of the double oxychlorides. In Fig. 12, No. 1 will give some idea of this spectrum.

The other double fluorides of this class yield similar spectra, the positions of whose brightest parts are given below. The barium salt shows the same structure in its bands as the potassium one, but the others exhibit only single blended bands. The following table will give the positions of the brightest line in each group in the various spectra, these being named in their order of brightness:—

Fluorescent Spectra of the Double Oxyfluorides.

Bands.	1.	2.	3.	4.	5.	6.	7.	8.
Potassio..	32°4	39°2	46°8	54°7	63°7	73°9	83°4	89°8
Bario ..	32°0	38°4	46°4	54°2	62°8	72°0	81°4	89°2
Ammonio	32°0	38°4	46°4	54°2	63°3	72°9	82°7	91°3
Sodio ..	30°4	38°8	47°6	57°2	66°1	76°0	86°4	—

The absorption spectrum of the potassio oxyfluoride is shown at 1 of Fig. 13.

Uranous Fluorides.

The salts of this class examined, were those first studied by one of us, and described fully in *Zeitschr. f. Chem.*, [2], ii., 353, and *Bul. Soc. Chim.*, 1866, ii., 450.

Uranous fluoride, UF_2
Potassio-uranous fluoride, $2(UF_2) + KF$
Sodio-uranous fluoride, $2(UF_2) + Na$

None of these show any fluorescence, but their absorption spectra are well worthy of note. That of the uranous

* Communicated by President Morton.

† [2], iii., 353; *Bul. Soc. Chim.*, 1866, ii., 450.

fluoride is shown in 2 of Fig. 14, and that of the potassio salt at 1 of the same figure. One of these (2), as will be observed, consists of broad undivided bands, and the other (1) of bands strongly marked with subdivisions. Both are easily seen by pressing the powder-like substances between slips of glass, either alone or with a little water.*

FIG. 12.

Oxyfluorides.

Uranic Formate.

This substance gives no fluorescence, and shows an absorption spectrum with faint bands located as follows:—83.5, 98.6, 106.6, 118.1, 129.2, 138.0.

FIG. 13.

Oxyfluorides.

Uranic Nitrate, $U_2O_3NO_3 + 6HO$.

The uranic nitrate fluoresces very brilliantly, and yields a spectrum of the same general character as the uranic acetate, sulphate, phosphate, &c.; in fact, the normal uranic spectrum. It also shows an absorption spectrum of well-marked and regularly disposed bands.

Both these spectra are well indicated in 1 of Fig. 1, with the exception that the absorption-band close upon F does not appear remarkably strong as the engraving might indicate, but, on the contrary, very weak. In the

Hagenbach*, and the former by Becquerel.† We have drawn attention already to the displacement suffered by the absorption-bands of this salt by change of solvent. Its neutral solution in water has a very faint fluorescence

Oxalates.

The salts of this class examined are the uranic oxalate, and the ammonio-, potassio-, and sodio-uranic oxalate.

The Uranic Oxalate, $2U_2O_3, C_4O_6 + 6HO$.—This is one of the salts observed by Stokes (See *Phil. Trans.*, 1852, part ii., p. 521). Its fluorescent spectrum is brilliant and well-marked, and consists of rather narrow bright bands showing what we have already described as the normal characteristics of uranic salts. The centres of its bands are located as follows:—

Fluorescent Spectrum of the Uranic Oxalate.

Bands.	1.	2.	3.	4.	5.	6.	7.
	40.0	48.8	47.5	67.0	77.0	89.3	

This salt has also a very well-marked absorption spectrum, in which the bands are regular in spacing and intensity. Their centres are located as follows, and are affected by solution and heat, as has been already stated, and is here shown.

Absorption Spectrum of Uranic Oxalate.

Bands.	1.	2.	3.	4.	5.	6.
Solid	98.0	108.0	118.8	130.0	139.6	152.0
Cold solution ..	97.5	107.8	118.4	127.4	137.2	150.6
Hot solution ..	97.0	107.4	117.3	125.5	136.0	148.2

The first three bands of this spectrum are very strong and black, and form a characteristic feature of the substance. They are the three noticed by Stokes.

Ammonio-Uranic Oxalate, $NH_4O, U_2O_3, C_4O_6 + 4HO$.—This salt is readily prepared by dissolving uranic oxalate in a solution of ammonia oxalate, and crystallises readily in strongly marked trimetric prisms. Its fluorescence is strong, and its bands are located as follows:—These bands resemble in appearance those of the double acetates, and the measurements are made at the brightest parts of each band.

Fluorescent-Bands of the Ammonio-Uranic Oxalate.

Bands.	1.	2.	3.	4.	5.	6.
	38.8	46.8	55.5	64.8	75.2	87.6

This salt shows also a well-marked absorption spectrum in which the bands (like those of the fluorescent spectrum just given) differ from the corresponding ones of the uranic oxalate by being much lower in the spectrum.

Absorption-Bands of the Ammonio-Uranic Oxalate.

Bands.	1.	2.	3.	4.	5.	6.
	96.4	106.6	117.6	124.0	136.0	148.0

FIG. 14.

Uranous Fluorides.

original drawing it was so marked to-keep out of the fluorescent-band, with which it is almost or quite coincident. The spectra are thoroughly discussed by

* Some portion of this work has been carried out after Dr. Bolton's departure for Europe, and in the present case, being unable to consult with him, I think it best to state, on my own responsibility only, a point which comes up in this place. The sodio-uranous fluoride prepared by Dr. Bolton shows the same spectrum as the uranic fluoride. In his original paper, Dr. Bolton marks it as doubtful, and, in noting its reactions, mentions some which agree exactly with those of uranic fluoride. I am therefore inclined to think that the material heretofore regarded as the sodio-uranous fluoride is a mixture.—H. M.

Potassio- and Sodio-Oxalates, $KOU_2O_3, C_4O_6 + 3HO$ and $NaOU_2O_3, C_4O_6 + 3HO$.—These salts are readily formed by dissolving uranic oxalate in solutions of potassic or sodic oxalate respectively. The potassic salt crystallises readily in large masses, forming monoclinic prisms, and the sodic salt in small crystals. The fluorescence of these was in both cases so weak that only three bright bands could be distinguished at all, and these seemed to correspond with the bands of the ammonia salt. The absorp-

* *Pogg. Ann.*, 1872, vol. cxlvii., p. 395.

† *Ann. de Chem. et de Phys.*, 1872, vol. xxvii., p. 569.

tion spectrum of the potassic salt was well defined as follows:—

Absorption-Bands of Potassio-Uranic Oxalate.

Bands.	1.	2.	3.	4.	5.	6.
	97.5	106.6	115.8	125.5	135.4	149.0

The sodio-uranic oxalate shows so feeble an absorption spectrum that three bands only can be recognised at 94.9, 104.6, and 116.5 respectively.

In solution, all these oxalates yield absorption spectra, which are very well marked and seem to be identical, carrying out the idea before suggested as to the breaking up of double salts when dissolved.

(To be continued.)

ON THE
ACTION OF BROMINE ON THE WATER-SALTS
OF SUCCINIC, MALIC, MALEIC, AND
PYRO-CITRIC ACIDS,

CRITICALLY EXAMINED AND INTERPRETED FROM THE
STANDPOINT OF THE "TYPO-NUCLEUS" THEORY.

By OTTO RICHTER, Ph.D.

In my two papers on the chemical constitution of succinic, malic, tartaric, and citric acids, I have endeavoured to embrace, by one theory, that particular section of mono- and poly-basic water-salts which are descended from the old fine-begotten polyatomic alcohols, and it is with the view of still more fully developing and substantiating that theory, that I have bethought myself of extending my speculative labours in a new direction, and with a different choice of materials. A rich and plentiful supply of suitable materials has been found to spring from the action of bromine on the water-salts of succinic, malic, maleic, and pyro-citric acids, as also on their pure or chlorinated anhydrides. This searching and powerful reagent is understood to vary greatly in its effects, according as it is administered in the dry state or in the presence of water; but, considering the vast magnitude of my subject, an exhaustive article on which would far exceed the limits of this paper, I have deemed it advisable to confine my remarks to the action of bromine on the aforesaid water-salts only, and while it is applied in a watery solution.

I may now state, by way of introduction, that my interpretation of this order of chemical phenomena is founded on the hypothesis that there exist three different modes or methods, according to which bromine in solution is capable of manifesting its chemical affinities. By the first of these methods, 2 molecules of bromine are supposed to unite directly with 2 mols. of water, with production of 2 mols. of bromo-peroxide of hydrogen, $2H_2Br_2O_2$, the oxygen of which is thus rendered more easily available for oxidising purposes, while the 2 mols. of hydrobromic acid are set at liberty or otherwise disposed of. By the second method, 2 mols. of bromine are supposed to combine directly with a given simple or complex carbon adjunct, and precisely in the same manner as 2 hydrogen molecules are wont to do, with this difference, however, that in the former case the recipient must always be a pure carbon adjunct, while in the latter case it may also be a hydrocarbon adjunct. By the third method, one of the 2 conspiring mols. of bromine is supposed to appropriate a molecule of hydrogen from a given simple or complex hydrocarbon adjunct, with formation of a molecule of hydrobromic acid, while the other molecule of bromine is made to step into its place.

This hypothesis of a threefold mode of action, of which bromine is susceptible, appears to me so natural and reasonable, that I have not scrupled to adopt it as a safe trustworthy guide while entering upon this new field of research. But before doing so, it is proper to state the programme I intend to follow consists of two

parts: in the first part I shall expound the molecular changes that accompany the action of bromine on the water-salts of succinic, malic, and maleic acids; in the second part I shall elucidate the molecular changes that attend the action of bromine on the water-salts of pyro-citric acid. Let us then, without further delay, examine into the contents of the first part.

PART I.

On the Principal Molecular Changes that Accompany the Action of Bromine on the Water-Salts of Succinic, Malic, and Maleic Acids.

When the ordinary succinate is treated with bromine, the resulting substitution products, chiefly amounting to two, are the bromo-succinate—

and the dibromo-succinate—

Both these compounds are engendered by the first method, consequently the accompanying molecular changes will consist, for the first compound, in the oxidation of the formous acid ally, at the expense of the newly-formed bromo-peroxide of hydrogen, and transposition of one of the hydrobromic acid molecules with the formylic alcohol principal, while the other is set at liberty; and, for the second compound, in the oxidation of the formous acid principal, and transposition of one of the hydrobromic acid molecules with the formylic alcohol ally, while the other is set at liberty.

When the ordinary malate is treated with bromine, the resulting substitution product is the bromo-malate—

where the same explanation holds good. This view of the molecular structure of the aforesaid brominated derivatives is also fully borne out by experiment. Thus, when a solution of the bromo-succinate is heated with oxide of silver, the bromide of that metal is precipitated, and the solution is found to hold the ordinary malate, clearly showing that the metamorphosis is accomplished by the newly-formed hydrate of silver transposing with the formyl-bromide principal. Similarly, when a salt of the dibromo-succinate is boiled with water or excess of base, the bromide of the metal is formed, in some cases with elimination of both bromine molecules, in others of one only. For instance, the soda-salt is, under this treatment observed to resolve itself into 1 mol. of sodium bromide and 1 mol. of bromo-malate of soda; whereas the silver-salt deposits 2 molecules of bromide of silver, while the inactive modification of the tartrate of water remains in solution. The baryta-salt, on the other hand, is found to differ from the two former salts in this respect, that by the loss of 2 mols. of water the previously-formed bromo-malate of baryta becomes converted into the bromo-maléate of baryta—

whence the bromo-maléate of water may be easily obtained with the aid of sulphate of water. The same compound may also be procured by heating the bibromo-succinate, a molecule of hydrobromic acid being expelled at the same time.

It would, further, be interesting to ascertain whether the oxymaléate, which Bourgoin professes to have realised by heating the bromo-maléate with oxide of silver, is identical with the tartrélate—

with which it shares the same formula.

Iso-bibromo-maléate—

Reverting again to the dibromo-succinate, it deserves to be noticed that this substance may likewise be produced by the action of bromine on the β -maléate (fumarate)—

In this reaction the first method is held to come again into operation, with this difference only, that the second molecule of hydrobromic acid, instead of being disengaged, is instantly made to react upon the freshly-formed deacetyl-bromide, with production of the de-ethylen-dibromide—

which, in conjunction with the two oxalic acid constituents, composes the dibromo-succinate. On the other hand, and in striking contrast therewith, it is found that, when the α -maléate—

is treated with bromine, by far the greater portion merges into the iso-dibromo-succinate—

while the small quantity of ortho-dibromo-succinate is evidently due to the admixture of the β -maléate, into which a corresponding portion of the α -maléate had previously been converted.

In order to explain the accompanying molecular changes, I have recourse to the second method, according to which the bromine unites directly with the complex carbon adjunct, so as to yield the compound—

Subsequently, 2 mols. of water suffer decomposition, their oxygen uniting with the formous acid principal, while their hydrogen, by acting upon the dibrominated carbon

adjunct in conformity with the third method, gives rise to a molecule of hydrobromic acid, which, by transposing with the colligated alcohol, produces the iso-dibromo-succinate as formulated above. When this substance is heated to 180°, it resolves itself into hydrobromic acid and the iso-bromo-maléate—

which may be regarded as a brominated derivative of the iso-maléate—

In this process the former constituent assumes the form of an acid carbon nucleus, while the residual bromo-methylen constituent re-unites with that nucleus as an adjunct. At the same time, the system undergoes that species of typical metamorphosis which transfers it from the class of alcohol-conjugated water-salts to the class of hydrocarbon-conjugated water-salts.

I may mention here, *en passant*, that the iso-maléate just alluded to was first obtained by Kämmerer from the iso-malate. This substance had been discovered in a silver-bath prepared for photographic purposes, and, on being treated with perchloride of phosphorus, gave rise to a chloride which, under the influence of water, resolved itself into hydrochloric acid and the iso-maléate in question.

I may further state that the action of bromine in excess on the succinate is observed to give birth to the iso-bromo-maléate—

which may be a direct substitution-product of the iso-bromo-maléate, or else a product of decomposition of a previously-formed iso-tribromo-succinate—

and I have no doubt that, ere long, and unless they have already been realised, the brominated derivatives of the malate and iso-malate will be added to our collection of curious and interesting chemical preparations. For their respective formulæ the reader is now referred to the annexed scheme (see preceding page).

(To be continued.)

NOTE ON THE COMPOUND OF STARCH WITH IODINE.

By E. SONSTADT.

SOME starch was kept for more than two months in a solution of salts containing more free iodine than the starch could take up. The iodised starch was then washed for a fortnight on a filter, by which time the water came through very nearly colourless; it was then further washed by decantation until the water was colourless after settling. The iodised starch thus prepared was black, and had little, if any, odour. A portion of it, air-dried, was found to contain 3·2 per cent of iodine. Another portion was then heated in an oven for a long while at a temperature somewhat higher than that of a water-bath. While drying, it smelt perceptibly of iodine, but, when thoroughly dry, it was perfectly free from odour, and the colour remained black. This stove-dried compound, heated in a closed tube, gave off no trace of free iodine, but a small quantity of a yellowish vapour came off, of a pungent odour, attacking the eyes, and condensing in the cool part of the tube in drops. The heat was then raised to redness, and the charcoal formed examined for iodine, which it proved to contain.

The stove-dried compound is extremely stable, and the ordinary reagents attack it very slowly; it could not be analysed by treatment with solution of thiosulphate of sodium, or of chlorine. A solution of the former, in excess, failed to decolourise it after a week's treatment, with frequent shaking. It was prepared for analysis by moistening it with a strong solution of hydrate of sodium, and heating to redness, and the iodine was estimated in the solution of the residue by chlorine-water. It contained 3·2 per cent of iodine, the same percentage of iodine as was contained in the air-dried specimen.

Another portion of the stove-dried compound was charred at a gentle heat, continued for about an hour, in a covered crucible, and at the last the heat was raised for about ten minutes to low redness. The charcoal proved, on analysis, to contain 3·2 per cent of iodine, equal to 19·64 per cent of the iodine contained in the specimen before its conversion into charcoal. Thus, about four-fifths of the iodine contained in the strongly-dried iodised starch is driven off (though not as free iodine) by charring at a red heat, and a fifth of the iodine remains with the charcoal formed.

ON THE ESTIMATION OF SULPHUR IN PIG-IRONS, &c.

By CHARLES H. PIESSE,
Public Analyst for the Strand District.

A SIMPLE and ready method of estimating the sulphur in pig-irons and steels, and one requiring but little attention, is as follows:—

Place into a beaker of about 300 c.c. capacity about 3·5 to 4 grms. of the sample, in drillings (weighed to within 0·01 grm. will be sufficiently accurate), and pour upon them 35 to 40 c.c. of aqua regia, consisting of 1 part HNO₃ with 2 parts HCl, maintaining the proportion of 10 c.c. of the mixed acids for every 1 grm. of the metal, keeping the beaker covered as well as possible with a clock-glass. After the first violence of the action has subsided, boil the liquid for a few moments until the whole of the iron is dissolved, then transfer the solution, with as little washing as may be, to a porcelain basin, and evaporate as nearly as possible to dryness on a water-bath. Treat the residue with some concentrated HCl, add about an equal bulk of water, and then filter. To the filtrate add a considerable excess of BaCl₂ solution, allow to stand for about twelve hours; filter, and weigh the precipitated BaSO₄ with the usual precautions. Multiply the weight of BaSO₄ found by 13·724, and divide the product by the weight of the iron employed; the result will be the percentage of S in the sample analysed.

Laboratory, 303, Strand, London.

NOTE FROM THE LABORATORY OF CHARING CROSS HOSPITAL.

By THOMAS BOLAS.

On the Ferrous Sulphate Test for Nitric Acid, and its Employment as an Approximate Indicator of the Amount of Nitrates in Potable Water.

IN performing this test, it is more advantageous to float the liquid under examination on a solution of ferrous sulphate in oil of vitriol, than to follow the usual method of floating an aqueous solution of ferrous sulphate on the suspected fluid mixed with oil of vitriol. The sulphuric solution of ferrous sulphate is best prepared by mixing oil of vitriol with 10 per cent (by volume) of a cold saturated solution of ferrous sulphate, and heating the mixture sufficiently to decompose any of the olive-green compound which may arise from the accidental presence of nitric acid in the oil of vitriol employed. When cold, the

colourless solution is ready for use, and it may be labelled "Nitric Acid Test." It is convenient to introduce the fluid to be tested by means of a pipette having the delivery-end bent once at a right angle, and the charged pipette should be placed against the side of the test-tube, about an eighth of an inch above the surface of the vitriolic solution, and then the finger should be removed from the upper end of the pipette to allow the liquid to flow. It is, moreover, necessary to use a pipette having a rather small opening, otherwise the rush of fluid causes considerable agitation.

By adopting this modification of the well-known sulphate of iron test, two principal advantages are attained—in the first place, it is unnecessary to test the sulphuric acid each time it is used, and, in the second place, the loss of time required to cool the usual mixture is avoided; moreover, the "nitric acid test," unlike aqueous ferrous sulphate, remains clear and always ready for use.

Attempts were made to estimate the nitric acid in potable waters by comparing the tints produced on floating them on "nitric acid test" with those produced when standard solutions of nitre are similarly treated, but in this case so much depends on delicacy of manipulation in pouring on the lighter fluid, that the results obtained were not so constant as might be desired, but if the water to be tested is carefully run in with a pipette as above described, and if the standard solutions of nitre are similarly treated, results are obtained which, in the course of a few seconds, indicate the approximate amount of nitrates contained in water. In cases where the amount of nitrates is small, a beaker may be advantageously substituted for a test-tube, and, in any case, the vessel in which the testing is performed should be steadily fixed during the operation.

The salt which separates on cooling the hot "nitric acid test" is under examination.

Charing Cross Hospital,
Nov. 10, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Moniteur Scientifique, du Dr. Quesneville,
October 1873.

Modern Progress of Industrial Chemistry.—Aimé Girard.—A popular address delivered at the Lyon meeting of the French Association for the Advancement of Science. It has been already noticed in the CHEMICAL NEWS.

Part Played by Septic Agents in the Animal System.—Fernand Papillon.—A physiological paper of considerable interest.

Theory of Tanning.—M. A. Reimer.—A continuation of the treatise which we have already noticed.

On Atmospheric Ozone.—M. Ebermayer.—An essay on the causes which promote the spread of epidemics, and the precautions to be adopted for their restriction.

Volumetric Determination of Bismuth.—MM. Buisson and Ferray.—The method in question is based upon the complete precipitation of bismuth by iodic acid in an acetic solution. The iodate of bismuth is a white anhydrous powder, $\text{Bi}_2\text{O}_3 \cdot 3\text{IO}_3$, insoluble in water and acids. This method is applicable to the determination of

all compounds into which bismuth enters. The assay of a sample of subnitrate of bismuth is made by dissolving half a gramme of this salt in a few drops of nitric acid, and diluting slightly with water. The liquid is saturated with bicarbonate of soda until a slight permanent precipitate appears. This precipitate is re-dissolved by acetic acid in excess so as to hinder the partial precipitation of bismuth on the subsequent addition of water. The liquid is then boiled and filtered to separate the iron and oxychloride of bismuth which may be present. To the filtrate we add 25 c.c. of iodic acid, and water enough to make up 250 c.c. It is well stirred, and after being allowed to settle for a few moments the liquid is poured upon a dry filter. To 100 c.c. of the clear liquid we add dilute sulphuric acid and iodide of potassium, so as to decompose the iodic acid which has not been consumed, and to re-dissolve the iodine set at liberty, which may be easily recognised when the liquid no longer contains greyish floating particles of iodine. The following equation explains this reaction:— $10\text{I}_5 + 5\text{KI} + 5\text{SO}_3 = 5\text{SO}_3\text{KO} + 6\text{I}$. Into the liquid containing the iodine there is dropped, by means of a burette graduated into tenths of a c.c., a solution of hyposulphite until the yellow tint of the iodine disappears. The addition of starch is needless, for the disappearance of the yellow tint is a more sensitive indication than the disappearance of the blue colour of the iodide of starch. The difference of the value found on acting upon iodic acid alone, and upon iodic acid after preliminary precipitation with a known weight of pure bismuth renders it possible to calculate the amount of bismuth contained in the sample under examination. It is preferable to express the result as metallic bismuth rather than as subnitrate, the composition of which is still not well known. The authors believe that it contains 68.94 per cent of the metal. If lead or baryta are present they must first be removed as sulphates. Tin and antimony found alloyed with bismuth are converted into insoluble stannic and antimonic acids by treatment with nitric acid. The reagents employed must be free from chlorine, and the iodide of potassium must contain no iodate of potassa. To detect the presence of this impurity dissolve 1 gm. of the sample in 11 c.c. of water, adding a few drops of pure hydrochloric acid, and shaking up with chloroform. If this latter body remains colourless the iodide is pure. The standard solution of iodic acid is prepared by dissolving 30 grms. of the crystalline acid in 1 litre of distilled water, and titrating with the aid of pure bismuth. The solution of iodide of potassium is saturated. The solution of hyposulphite is sufficiently strong when 30 to 40 c.c. serve to oxidise the iodine liberated from 10 c.c. of iodic acid.

Bulletin de la Société Française de Photographie,
No. 9, 1873.

Notice on Heliography.—M. de Saint-Florent.—The author has succeeded in producing heliographic proofs, whose colours have the closest relation with the natural colours. Landscapes have been obtained in this manner in the camera, though the colours were rather faint. He steeps a sheet of paper of fine texture in—

Nitrate of silver	20
Distilled water	20

To which, when dissolved, is added—

Alcohol	100
Nitric acid	10

When the paper is dry it is again plunged into—

Hydrochloric acid	50
Alcohol	50
Nitrate of uranium	1

It is necessary to dissolve previously in the hydrochloric acid a little zinc-white, say from 1 to 2 grms. On removal from the bath the paper is exposed to sunlight until it turns a violet-blue. It is then, after drying, plunged anew first into the silver, and then into the hydrochloric bath.

The operations are repeated till a paper is obtained of an intense violet-blue. When quite dry it is placed in the following bath:—Water, 100; acid nitrate of mercury, 4 to 5 drops. The paper is left in this bath five to ten minutes and dried. It is then exposed under a coloured glass, and there is obtained in thirty to forty seconds a proof with a white ground and all the colours of the model. The colours are brighter, and the speed as great if to the foregoing bath be added—

Bichromate of potash (saturated solution) ..	2
Sulphuric acid	2
Chlorate of potassa	1

To fix the image approximately it is washed in much water, and then plunged in—

Ammonia	5
Alcohol	100

The paper is washed and plunged in a saturated solution of an alkaline chloride. After a further washing the proof resists diffused light for a long time. More rapid action is obtained if the chloride of silver paper is allowed to blacken under violet or blue glasses. If on withdrawal from the bath of nitrate of mercury the paper is exposed under a coloured glass, and glasses of different colours are interposed between it and the sun, the proof comes up more rapidly under yellow, green, and red glasses than under blue and violet. To produce landscapes with the camera it is necessary to prevent as far as possible the action of diffused light, and for this purpose to adapt in front of the objective a cardboard cone of suitable length. The time of exposure, with a Darlot's objective of 0.2 metre focal distance, is from fifteen minutes to one hour, using the largest diaphragm, and operating in sunshine.

Proofs with Fatty Inks.—An account of certain specimens sent by M. Rodrigues of the Polytechnic School of Lisbon.

An Account of the Process for Photo-zincography as Employed by the Photographic Section of the General Direction of Geographical Works of Portugal.—The mixture used in the preparation of the plates was—

Water	1000	grms.
Gum arabic	40	"
Sulphate of copper	2	"
Gallic acid	5	"
Nitric acid	0.5	"

Dry Collodion Process.—A. de Constant.—The author indicates the conditions necessary for successful work by this process. He recommends the employment of a special collodion made with a cotton prepared at a high temperature, or else already old; to find a covering which whilst acting mechanically to preserve the porosity of the collodion contains also a chemical agent which may intervene usefully for the preservation of the layer, and may aid in the combination of the development; to compose the preparation chosen for covering, so that the dry layer may not contain any element of alteration, and may remain in good condition for some months; to find a means of softening the dried layer, and of restoring to it a sufficient permeability that the developing solution may penetrate and exert its action equally and completely, without making rapidly a capital question, to abridge the exposure as much as possible. Into each of these points the author is about to enter in detail.

Stereoscopic Proofs on Glass, and Various Procedures.—Count Ludovico de Courten.—The author prefers plates preserved with tannin, which he prepares exactly as directed in his "Manuel Pratique." He gives procedures also for cementing positive proofs upon cardboard, for securing solidity in the varnish applied to negative proofs, and for producing moonlight effects.

The Ordinary Wet Collodion Process.—M. Th. Sutton.—The author has been experimenting in order to ascertain with precision the best respective proportions for the soluble iodide and bromide in the wet collodion pro-

cess. He concludes that a collodion for great rapidity ought to be liberally iodised, and to contain a fair proportion of bromine. The strength of the nitrate bath should not exceed 8 per cent. The bromide of silver he finds is exceedingly sensitive to light without the presence of free nitrate, and this will be the starting-point for a great improvement in the art. The author makes use of a bath prepared more than ten years ago, and which has been in use ever since. He employs pure neutral re-crystallised nitrate, and adds from time to time bicarbonate of soda to the bath, exposing it for a day to the light. The carbonate of silver is then filtered off, and the bath, slightly acidulated with nitrate of silver, is in excellent condition.

Reimann's Fürber Zeitung, No. 36, 1873.

The Exhibition in Vienna.—Haabl and Co., of Molenbek (Belgium), exhibit a model of an apparatus for extracting the grease from wool by means of bisulphide of carbon. Schlumberger, of Brussels, exhibits xanthin, artificial indigo, and other coal-tar products. There are receipts for colours upon plush, scarlet, ponceau, crimson, garnet, and medium garnet. The "scarlet spirit" used as a mordant in these formulæ is directed to be made from 14 lbs. tin crystals, 24 lbs. bichloride of tin, and 50 lbs. of hydrochloric acid, fuming, but free from iron. Only the clear part of the mixture is to be employed. There is an article on the arrangement of steam pipes in dye-works, which contains nothing new to English dyers. Next follow receipts for dyeing cotton a chamois; cotton-yarn a rose by means of annatto and safflower extract; mixed goods a grey; wool a drap, a stone, and a reseda. Reichardt has found, at Jena, sausages dyed with magenta. In this case alcohol extracts the red colour. The so-called "antimony-blue" has been going the round of the technological papers.

No. 37, 1873.

This number contains a full description, with illustration, of Haubold's machine for washing yarn. There are receipts for garnet, light, medium, and dark green, and silver-grey on plush, porcelain white and lemon-yellow on wool. Catechu and sanders are recommended as an addition to the copperas vat in order to save indigo. Next follow prescriptions for steam-printing colours, chiefly olives.

No. 38, 1873.

The New Indigo Vat.—Schützenberger and De Lalande.—It is known that the low stage of oxidation of sulphur obtained on the reduction of sulphurous acid with zinc dissolves indigo. On this reaction the following procedures for dyeing and printing with indigo are founded:—To prepare the reducing liquid a solution of bisulphite of soda at 35° B. is brought in contact with sheet zinc in a closed vessel, of which the liquid should occupy only one-fourth. After the lapse of an hour the zinc is precipitated from the clear liquid by means of milk of lime. It is then diluted and decanted or filtered with exclusion of air. The clear liquid is then poured upon the ground indigo, with the addition of the needful soda and lime. 1 kilo. of indigo yields in this manner a very concentrated vat of 10 to 15 litres. Cotton is dyed cold, and wool with the aid of heat. A vat is filled with water, and a suitable quantity of the above indigo mixture introduced, when the dyeing can be performed at once. The excess of the low sulphur acid dissolves the froth which appears on the surface. During the process of dyeing further quantities of indigo can be added as required. Cotton can be rapidly and easily dyed in this manner; and in the case of wool the dyer escapes the many disadvantages of the hot vat, and obtains brighter and clearer shades. To print a fast blue the alkaline solution of the reduced indigo is printed on with an excess of the reducing agent, aged for twelve to twenty-four hours, washed, and soaped. In comparison with the old process there is a saving of indigo to the extent of 50 to 60 per cent; the shades are richer and the impressions sharper. The colour requires no subsequent

treatment, and can, therefore, be printed on simultaneously with most other colours.

Cotton Dyeing.—There are receipts for a deep rose, a safflower-scarlet, an olive, and a violet on cotton yarns.

Alpaca and Mixed Goods.—The editor gives receipts for a cochineal scarlet, a dark brown, and a black.

Wool Dyeing.—There is a receipt for a Nicholson blue. Woollen piece goods are directed to be worked in a solution of 1 per cent of the colour, and $\frac{1}{2}$ per cent of sulphate of zinc, while the temperature is slowly raised to a boil, which is maintained for an hour. The cloth is taken out, cooled, rinsed in cold water, and placed in a beck containing 2 per cent (on the weight of the goods) of sulphuric acid, and $\frac{1}{2}$ per cent of sulphate of zinc. A single turn in this bath suffices to raise the colour.

Plush Dyeing.—There are receipts for a dahlia, and a magenta and a blue.

Silk Dyeing.—There are receipts for a rose and a sky-blue, which offer nothing remarkable.

Argentine Effect.—Jacobsen stirs up commercial tin (zinc?) powder with a solution of albumen to a paste, which is then printed. The goods are steamed and steeped in a solution of bichloride of tin. The tin dissolves out the zinc, and is deposited in its place. The goods are washed, dried, and run through a glazing machine which polishes the tin. It is proposed—rather grotesquely—to dye drabs and browns with an extract of green walnut shells! Sulphide of cadmium as an undried precipitate, is found to be a good (but expensive) yellow colour for soaps. A permanent red ink is prepared by rubbing up carmine with a solution of soluble glass to the consistence of good writing ink. The writing dries swiftly, and is as bright as a mirror. This ink must be preserved from contact with air. Solution of gum arabic is improved by adding 2 parts of sulphate of alumina to 250 of a solution of gum, made in the proportion of 2 parts of gum to 5 of water. Gum thus prepared is sold as vegetable glue, and serves to cement together surfaces of metal and glass. Dufrené to prevent mouldiness steepes the articles in a dilute solution of tannin, and treats them with a solution of bichromate of potassa till a brown colour is produced. He then washes and dries. (It must be remembered that this process is not applicable to articles of food.)

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 38, 1873.

The greater part of this number is again filled up with non-chemical matter. There is a notice of Siemens's gas-furnaces, which are no longer a novelty, and a short paper on the new process for the manufacture of alkali as worked by M. Solvay, at Couillet, in Belgium. This process, founded on the decomposition of the chloride of sodium by the bicarbonate of ammonia, has been already in operation at Couillet for some time, and now furnishes about one-fourth of the soda actually consumed in Belgium. Hence it is evident that M. Solvay has overcome the difficulties which former inventors such as Turech, Schlössing, and Roland found insurmountable. M. Solvay has received a diploma of honour at the Vienna Exhibition.

No. 39, 1873.

This number again contains no chemical matter.

Revue Scientifique de la France et de l'Etranger,
Octobre 18, 1873.

History of the Chemical Theories of Digestion.—Claude Bernard.—Prof. Claude Bernard, in his course of lectures on general physiology, gives an account of the various theories of digestion entertained by men of science from Hippocrates downwards. The eminent Greek physician considered digestion as a cooking process. Galen maintained the existence of three kinds of digestion, the first performed in the stomach, the second in the duodenum,

and the third in the liver; a view taken in later times by Servetus and Drake. Plistonius, a disciple of Protogoras, identified digestion with putrefaction. Hilmon regarded digestion as fermentation, and divided it into six kinds, a view in which he was followed by Sylvius, Willis, Boyle, and others. The mechanical theory of Borelli, Boerhaave, and Pitcairn considered digestion to be mere trituration, a view which as far as animal food is concerned was experimentally refuted by Reaumur. This naturalist introduced into the gizzards of birds portions of meat enclosed in perforated metals tubes. On killing the bird after some time the meat was found to have been dissolved. Seeds, however, enclosed in a similar manner resisted the digestive process. Spallanzani succeeded in withdrawing gastric juice from animals, and by its means performed artificial digestion outside the living body. The author concludes with a notice of the observations made upon the celebrated Alexis St. Martin.

October 25, 1873.

This number contains no chemical matter.

NOTES AND QUERIES.

Notes on the Utilisation of Sewage.—(From the "Report of the Main Drainage Committee for 1864," vol. 487).

2163. (To Mr. West). Can you give us any information of the relative cost of the carriage of any substance, such as clay, in a cart, or by suspension in water, by means of pumping?—That will make no difference at all, because we are pumping all the China clay in St. Austell, which is about 200,000 tons a year, and that is thicker than the mud of the Thames, and it does not interfere with the valves at all as long as it is in a liquid state. We pump the mineral water in some of the mines also; half of that is entirely what we call mud.

2175. Does your estimate of the price of pumping depend upon a given price of coals?—Yes, entirely so. I calculate the coals would cost £1 per ton, which is quite sufficient.

2178. (To the same). You have stated that the liquid clay is conveyed in pipes by gravitation; what distance is it so conveyed?—From two to three miles in several places. I have one gentleman close by my land now, about two miles off, who is a large clay merchant, and he tells me that he saves something like £800 a year by carrying the clay in this manner.

2209. (To Mr. Hocking). You stated that if the coal were dearer as between your average of 17s. and 20s., that would increase the cost of lifting; are there not other elements besides coal, such as wear and labour?—We have calculated for labour the price generally paid in this neighbourhood, but the increased price for lifting would not increase in the same ratio as the price of coal increased.

2210. Nor would the wear and tear of the engines?—No.

2211. Then should we have simply to add the cost of coal?—Yes.

2212. What is the maximum height to which you can lift the sewage?—It would be lifted 300 feet in one lift, but I do not think it would be advisable to lift it to that height in one time.

2213. Would it require much stronger pumps for that height?—Yes.

2214. You would require other engines, and another reservoir at the next lift, would you not?—Yes.

2385. (To Mr. Johnson). Upon what data do you ground your opinion that the sewage will not answer when applied to corn crops?—The advantage of sewage, I take it, to grass, is to be divided into two portions: first, the advantage of applying so much pure water; and, secondly, the application of the various matters which are mechanically suspended in, or chemically combined with, that water in the case of sewage. I take it that, in most cases, if the same bulk of water were applied to grass land, it would do a great deal of good in the majority of instances in suitable soils; but with regard to the cereals you do not want moisture; the driest climates are the best for the most valuable of these cereals, and therefore when you add water to corn land it is adding what the land does not need.

2386. But does not corn land require the fertilising properties of sewage?—Yes; but then I take it that the bulk of water which would be necessary to carry those ammoniacal matters, and that small amount of phosphate of lime which is contained in the sewage, is so great, that the water would be injurious to perhaps a greater extent than the chemical matters would do good to the land.

2597. (To Mr. Ellis). Do you know of any chemical manufacture at Alnwick?—I cannot say as to that. At Edinburgh they put on considerably more than £100 worth of sewage to the acre, and they only get £30 worth of grass. That is a great failure.

2666. (To Mr. Bateman). Have you found any inconvenience from the application of the sewage?—There has been no inconvenience; the most beautiful application of sewage that I have seen is at Carlisle.

MEETINGS FOR THE WEEK.

THURSDAY, 20th.—Chemical, 8. E. Davies, "On the Chemical Properties of Ammoniated Ammonia Nitrate." Dr. W. J. Russell, "On the Action of Hydrogen on Silver Nitrate."

Now Ready, Price 5s.,
Milk-Analysis.—A Practical Treatise on the
Examination of Milk (including Cream, Butter, and Cheese).
By J. ALFRED WANKLYN, M.R.C.S., Corresponding Member of the
Royal Bavarian Academy of Sciences, Public Analyst for Bucks.

London: TRUBNER and CO., Ludgate Hill.

Chemical Technology, or Chemistry in its
Applications to the Arts and Manufactures. By THOMAS
RICHARDSON and HENRY WATTS. Second Edition, illustrated with
numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.
Nature and Properties of Fuel: Secondary Products obtained from
Fuel: Production of Light: Secondary Products of the Gas Manu-
facture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.
Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching
Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.
Aluminium and Sodium: Stannates, Tungstates, Chromates, and
Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-
Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appen-
dices containing the latest information and specifications relating to
the materials described in Parts 3 and 4.

BAILLIERE and CO., 20, King William Street, Strand.

Analysis of Food, Water, and Air.—Mr.
WANKLYN has opened a Laboratory at 117, Charlotte Street,
Fitzroy Square, and is prepared to give Practical Instruction in
Chemical Analysis to Medical Officers of Health, and to persons
proposing to undertake the duties of Public Analysts under the new Act.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared
to give Instruction in all branches of PRACTICAL
CHEMISTRY, particularly in its application to MEDICINE,
AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five
o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every
description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews
the Laboratory, 60, Gower Street Bedford Square, W.C.

Royal Polytechnic Institution, 309, Regent
Street.—Laboratory (entirely re-fitted) and Class-Rooms are
now open.

ASSAYS, ANALYSES and Investigations connected with
PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are
offered to persons preparing for GOVERNMENT EXAMINA-
TIONS.

Classes are now forming for Practical Study in CHEMISTRY
STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S. M.S.A.
at the Institution.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES
under the direction of Professor E. V. GARDNER, F.E.S., &c.
of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and
and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other
examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with
Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

South London School of Chemistry and
Pharmacy. Director—Dr. JOHN MUTER, F.C.S.

Hours of Lecture for Session 1872-73:—

Chemistry (Inorganic) .. 10 a.m.	Materia Medica .. 4 p.m.
(Organic) .. 2 p.m.	Pharmacy .. 2 p.m.
Botany (Structural) .. 11 a.m.	Classics (Junior) .. 9 a.m.
(Systematic) .. 3 p.m.	(Senior) .. 4 p.m.

Laboratory open for Practical Chemistry from 10 till 4.

This School affords the most eligible opportunities for obtaining at
once a rapid, complete, and practical knowledge of the subjects taught.
All the fees are perpetual until the examination in view is passed,
without reference to time. Country Students visiting London are
placed in Lodgings registered by the Secretary, where no impositions
are permitted to be practised, and where the prices are all on a fixed
moderate scale. For terms, apply to the Director, or to

W. BAXTER, Secretary.

231 and 285, Kennington Road, S.E.

North London School of Chemistry, Phar-
macy, &c. Established 12 years.—Conducted by Mr. J. C.
BRAITHWAITE, for thirteen years Principal Instructor in the
Laboratories of the Pharmaceutical Society of Great Britain, and
Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1873-1874 commences on the 1st of October, when—
The LABORATORY will be open for Instruction in Practical
Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms
moderate.

The CLASSES for CHEMISTRY, MATERIA MEDICA
BOTANY, and LATIN, meet as usual at 8 p.m.

Fee to either Class Half-a-Guinea per Month. Pupils desirous of
doing so can attend until qualified for one inclusive Fee.

The BOTANICAL GARDEN affords every facility to Students
desirous of acquiring a Practical Knowledge of Botany. During the
Season BOTANICAL EXCURSIONS are made every Saturday
at 10 a.m.

As each Pupil works independently, he can enter at any period to
either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the Preliminary Modified Minor and
Major Examinations, &c.

A few Pupils received to Board in the house.

Applications, accompanied with a stamped envelope, addressed to—
54, KENTISH TOWN ROAD, N.W.

Theoretical and Practical Chemistry.—

Mr. SIDNEY W. RICH, Analytical and Consulting Chemist,
undertakes all kinds of Analyses, including the Analysis of Water,
of articles of Food and Drink, and of Commercial Articles.

Mr. RICH also undertakes Investigations relating to Patents,
Manufactures, &c. Gentlemen who wish to carry out Investigations
personally may have a separate room if privacy be needed.

PRACTICAL CLASSES commence in October, January, and
March, but laboratory pupils who work independently may enter at
any time.

Further Particulars may be obtained at the Laboratory, 1A, CHE-
NIES STREET, TOTTENHAM COURT ROAD, LONDON
W.C.

"HEAT IS LIFE."

NICHOLLS'
PATENT VOLTA MEDICATED CLOTH
CURES NEURALGIA IN FIVE MINUTES.
RHEUMATISM, AND GOUT, NO MATTER OF
HOW LONG STANDING.

NICHOLLS' PATENT VOLTA MEDI-
CATED CLOTH CURES all DISEASES through the
medium of the Nervous System.

This system is now acknowledged by the Profession to be the
highest and most certain treatment of diseases at present known to the
medical world.

It has now supplied a want which JOHN HUNTER, Mr. ASHESMETHY,
and other eminent medical men confessed was lacking, viz. the means
of generating, exciting, and maintaining Capillary Action by Caloric
Heat, which every medical man knows the absolute importance of.

No person should be without this invaluable invention. It is un-
doubtedly the most important discovery in medicine ever brought to
light.

NICHOLLS' PATENT VOLTA MEDICATED CLOTH is
sold in boxes at 1s. 1d., 2s. 6d., 4s. 6d., 11s., and 22s. Apply at the
Chief Depot, 292, High Holborn; or order it through your Chemist.

A Box of Nicholls' Volta Cloth sent on receipt of 15 stamps.

NICHOLLS' STIMULANT for the NERVES is invaluable as an
adjunct to be taken whilst using the Volta Cloth. Sold in bottles
at 1s., 2s. 6d., and 4s. each. Warranted free from alcohol, unfermenting,
and non-intoxicating.

TESTIMONIALS.

19 and 21, Paternoster Row, London, May 15th, 1871.

MR. NICHOLLS.—Dear Sir,—I tried your Application for total deaf-
ness of the left ear and it took it away. My daughter tried it for
toothache—same result.—Yours truly, B. WILLIAMS, Music Publisher

North Road, Highgate, Jan. 9th, 1873.

MR. NICHOLLS.—Dear Sir,—I tried your Application for Gout, from
which I have long suffered. I have not had the slightest return of
it. With many thanks, I remain, yours truly, WILLIAM ATKINS.

42, Tavistock Terrace, Upper Holloway, 10th April, 1873.

Dear Sir,—Your Cloth has been very beneficial to me. Last
Thursday I sent your address to Dr. Boulton, of St. John's Hall,
Highbury, and I now send my daughter for a Cloth for an old friend
friend of mine—a Gout Cloth.—Yours truly, W. MARLER.

These and many more genuine Testimonials can be seen at the
Chief Depot, 292, High Holborn.

R. NICHOLLS, 292, High Holborn.

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 729.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 6, 1873.

Dr. ODLING, F.R.S., President, in the Chair.

THE minutes of the previous meeting having been read, Messrs. Walter Odling and C. W. Vincent were formally admitted Fellows of the Society.

The donations to the Society were then announced by the Secretary, and the following names read for the first time—Messrs. Charles L. Field, Walter T. Goolden, B.A., B. W. Richardson, F.R.S., Donato Tommasi, Edgar Beckett Truman, Thomas H. Davies, William Masters, A. Campbell Dixon, James Baynes, Thomas Jamieson, Robert Williamson, Charles James Hislop Warden, Francis Jones, Sydney Knowles Muspratt, Felix M. Rimmingtons, Edward Clemenishaw, Samuel Herbert Cox, and Arthur B. Kitchener.

For the third time—Messrs. Edward Collens, George Bult Francis, William Edward Porter, John Turner, and William Charles Young, who were ballotted for and duly elected.

Dr. ODLING said it was not customary for the President to address the Fellows at the first meeting of the session, but he could not help saying a few words of welcome and congratulation on their taking possession of their new rooms, and they might regard the assistance they had received from the State, unaccompanied as it was by State control, as some recognition of the advantages of scientific research to the national welfare, and as tending to the mental and moral cultivation of the people. It was necessary for them to have some place of meeting, and it would be impossible for them to provide such handsome rooms as they had now, indeed to provide rooms at all would be a very serious inroad on their funds. He might mention two new features—one the commodious store-room for the spare numbers of their journal, and the other the laboratory adjoining the meeting-room, the primary use of which would be for giving experimental illustrations in connection with the papers brought before the Society. After alluding to the various benefits to be derived from their meeting together, the speaker said that chemical science treated of things that could be handled, and phenomena which could be observed, and the use of the laboratory was offered to those who brought new facts before the Society to illustrate those facts, for we all know the great light and interest chemists take in witnessing such experiments. With regard to the financial aspect of the matter, they had incurred considerable expense, although the Government had given the gas-fittings and the new book-shelves in the library; however, all that was useful in the old rooms had been removed here, and utilised in one way or other; even the old historic seats, which were formerly those of the Royal Society, formed part of the benches in that room. He could not but tell the Fellows that it was owing to the great exertions of the Junior Secretary, Dr. Russell, that they were enabled to remove to their new rooms in time for this meeting, and throughout the arrangements they had met with the greatest courtesy and kindness both from Mr. Barry, the architect, and also from the Clerk of the Works.

The first paper, "On the Optical Properties of some Modifications of the Cinchona Alkaloids," by D. HOWARD, was read by the author. After enumerating the various observations that had been already made on this subject, he drew attention to the approximate relation between the deviation caused by quinin and cinchonin and the alkaloids from which they are derived; thus the mean of the specific rotary power of quinine and quinidin in alcoholic solution is 47° to the right, and that of quinicin, corrected for its combined water, 41° , whilst, in aqueous sulphuric acid, they are 20.5° and 19.4° respectively. A similar approximation is found to be the case with cinchonin as compared with cinchonin and cinchonidin. The action of nascent hydrogen on the alkaloids in acid solution gives rise to compounds which Schützenberger regards as differing from the original compound in containing 1 atom more water; the author, however, is inclined to doubt this, as no evolution of hydrogen occurs when cinchonin or cinchonidin is treated with zinc and dilute sulphuric acid until a considerable excess of the acid has been added: the optical properties of the bodies formed are very similar to those of quinicin and cinchonin. The author then proceeded to describe the method of preparation and optical properties of the various ethyl bases produced by the action of ethyl iodide or bromide on the cinchona alkaloids: the rotation produced by the salts of the ethyl bases is in most cases very nearly proportional to that which would be given by a salt of the original alkaloid, equal in amount to that contained in the new compound.

THE PRESIDENT thanked the author in the name of the Society for his interesting memoir, and hoped he would take advantage of his great opportunities, and give the Society some further results of his experiments.

Dr. FRANKLAND had listened with much interest to Mr. Howard's account of the alteration produced on the polarised ray by the effect of combination. It was a matter of great importance to accumulate results on this subject, so as to endeavour to ascertain what circular polarisation means, chemically speaking. The alteration in the intensity is not only produced by combining two substances of opposite rotary powers, but sometimes also by the combination of a rotary body with a neutral one. He would like to ask the author whether he had ever observed amongst the cinchona alkaloids an instance in which combination with an indifferent body had caused a reversal of the rotation of the polarised ray.

Dr. WRIGHT suggested to the author that he should determine the heat of combustion of some of these isomerides, to see whether there was any relation between the heat evolved and the rotary power, somewhat similar to that which had been observed in many volatile bodies between the heat of combustion, and the boiling-point.

Mr. HOWARD replied that he had not found any instance in which inversion of the rotary power took place where the altered compound could be re-converted into the original substance. In dealing with bodies of so complex a nature and so delicate a structure, which were so very easily destroyed, the difficulty was to find cases where they give satisfactory results at all.

Dr. C. R. A. WRIGHT then read a "Preliminary Notice on the Oils of Wormwood and Citronella." The portion of oil of wormwood boiling between 195° and 200° , and termed by Gladstone *absinthol*, $C_{10}H_{16}O$, when treated with phosphorus pentasulphide, is decomposed, a hydrocarbon being produced which boils at 170° to 180° , and a yellowish oil boiling at 230° and upwards. The hydrocarbon, after purification, boiled at about 176° , and, on analysis, appeared to be cymen, produced in the reaction—

The yellowish liquid boils at about 235° , and is chiefly *thio-cymen* or *cymyl-sulphhydrate*, identical with that recently obtained by Fliesch from camphor. Oil of citronella, when distilled, yields an unstable body of the formula

$C_{10}H_{18}O$, which unites with bromine, and the product, $C_{10}H_{18}Br_2O$, when heated, splits up thus—

The resulting cymen is apparently identical with that already known.

The PRESIDENT, having thanked the author for his communication, called on Mr. W. F. DONKIN to read his paper "*On the Estimation of Nitrates in Potable Waters*," This process is founded on the reaction that a nitrate in the presence of chlorides, when treated with phenol and sulphuric acid, gives a reddish solution, which, on the addition of an excess of ammonia, changes to a more or less decided blue; this gradually becomes more intense on standing. The water under examination is compared with a standard solution of potassium nitrate containing a known quantity of the salt; these are treated in a precisely similar manner. The process is capable of accurately determining the amount of nitrates present to within 1 part in 4,000,000 of water; it is, however, necessary to closely observe certain details given in the paper, in order to insure this result, slight variations in the manner of conducting the operations or in the quantities of the reagents employed producing corresponding variations in the depth of tint obtained.

Dr. ODLING said the determination of the amount of nitrates in water was a subject of interest to many of the Fellows present, and if an easy process for determining ammonia could be devised, it would be a boon to water analysts all over the country.

Dr. FRANKLAND remarked that, although much attention had been devoted to the determination of nitrates and nitrites in waters, there was still room for another process. The aluminium process answered admirably with a water which gave a large residue with comparatively little organic matter, and the mercury and sulphuric acid process when much nitrate was present, but it was not trustworthy when the amount of the latter was very small. In those cases where there was a large residue and a large amount of organic matter, he hoped the new process might prove available, but he thought the accuracy of the method had not been pushed far enough. The mercury process fails when the amount present in the water is less than 0.01 in 100,000. He would like to ask the author whether he had made any experiments on such minute quantities.

Mr. W. THORP congratulated Mr. Donkin on obtaining such good results with a colour process, the difference detected being about 1½ per cent on the total quantity, whilst with the Neseler test it required a practised eye to detect a difference of 2½ per cent. He thought, when the amount of nitrates was but small, that the mercury and sulphuric process was rendered thoroughly satisfactory by adding a known quantity of a standard solution of a nitrate to the water previous to evaporation, the object being to obtain a measurable quantity of gas, thus overcoming the difficulties which were merely mechanical.

Mr. DONKIN, in answer to Dr. Frankland, said he had not made further experiments on very small quantities of nitrates: he had examined a water containing a large amount of residue, which yielded a faint blue tint, but had not tested for nitrates by any other process. One of the great advantages of the method was its rapidity; half-a-dozen determinations could easily be made in a morning.

The Secretary then read a "*Note on the Action of Iodine Trichloride upon Carbon Disulphide*," by Mr. J. B. HANNAY. The author finds that the result of the action of pure carbon disulphide on iodine trichloride is represented by the equation—

and suggests that the different results obtained by Weber were probably owing to the iodine trichloride he employed containing monochloride. The author prepares the pure trichloride by passing chlorine over iodine in a retort, with occasional agitation, until a reddish yellow solid is produced. Heat is then applied, and a yellow sublimate of the trichloride is formed in the receiver, whilst mono-

chloride is left behind; this is again chlorinated, and again sublimed, until the whole is transformed into the trichloride.

The PRESIDENT, after expressing thanks for Mr. Hannay's paper, adjourned the meeting until Thursday, the 20th of November.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, November 3rd., 1873.

GEORGE BUSK, F.R.S., Treasurer in the Chair.

THE Secretary announced the decease of Sir Henry Holland, the President, on October 27.

Henry Adolphus Focking, and Major John Andover Wood were elected Members of the Royal Institution.

The special thanks of the members were given to Charles Woodward, F.R.S., for his present of his work on the "*Polarisation of Light*," and of much valuable apparatus illustrating the subject; and also to William Salmon, M.R.I. for his donation of ten pounds for the promotion of scientific research in the Royal Institution.

The presents received since the last meeting were laid on the table, and the thanks of the members returned for the same.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 7th, 1873.

E. W. BINNEY, F.R.S., F.G.S., Vice-President, in the Chair.

MR. SAMUEL BROUGHTON was elected Treasurer of the Society in place of the late Mr. Thomas Carrick.

"*Atmospheric Refraction and the Last Rays of the Setting Sun*," by DAVID WINSTANLEY.

It is recorded in the Proceedings of this Society that a letter dated from Southport, and written by Dr. Joule, was read at the meeting held on the 5th October, 1869. In that letter it is remarked that "Mr. Baxendell noticed the fact that at the moment of the departure of the sun below the horizon the last glimpse is coloured bluish-green." Dr. Joule also observes that on two or three occasions he had himself noticed the phenomenon in question, and that "just at the upper edge where bands of the sun's disc are separated one after the other by refraction, each band becomes coloured blue just before it vanishes."

During the past eighteen months the writer, from his residence in Blackpool, has had frequent opportunities of observing the setting sun, and has noticed the phenomenon of the final coloured ray certainly more than fifty times. To the naked eye its appearance has generally been that of a green spark of large size and great intensity, very similar to one of the effects seen when the sun shines upon a well-cut diamond. The colour, however, is by no means constant, being often, as in the case of Mr. Baxendell's observation, bluish-green, and at times is mentioned by Dr. Joule, quite blue. The period of its duration, too, is likewise variable. Sometimes it lasts but half a second, ordinarily perhaps a second and a quarter, and occasionally as much as two seconds and a half.

When examined with the assistance of a telescope, it becomes evident that the green ray results at a certain stage of the solar obscuration, for it begins at the points or cusps of the visible segment of the sun, and when the "setting" is nearly complete extends from both cusps to the central space between, where it produces the momentary and intense spark of coloured light visible to the unaided eye.

From the fact of the green cusps being rounded I apprehend that irradiation contributes to the apparent

magnitude of what is seen. The range of colour, too, as seen in the telescope, is more varied, and the duration of the whole phenomenon more extended, than when the observation is made only with the naked eye.

Of the objective nature of the phenomenon it is needless to offer evidence; for it needs to be but seldom seen to preclude the idea of an optical illusion. That the waters of the ocean have nothing to do with the production of the colour is made manifest by its visibility when the sun "sets" behind the edge of a well-defined cloud. On the 14th and 15th of June, for instance, it was seen at upper contact of the solar limb with clouds. On the earlier date in question a thin band of cloud stretched across the setting sun, and under a power of fifteen diameters the green effect was seen at upper contact with the cloud, and again at final disappearance below the horizon. On the later date it was again seen at upper contact with each of several filaments of cloud, and again at final disappearance. And on several other occasions the writer has observed the effect when the disappearance of the sun has taken place at an elevation of six or eight degrees behind a heavy bank of clouds.

Respecting the increased range of colours seen when the phenomenon is observed with telescopic aid, I may mention that on the 28th of June the sea was calm and the sky quite cloudless at the setting of the sun. Of the final coloured rays fifteen diameters showed the first to be a full and splendid yellow, which was speedily followed by the usual green, and then, for a second and a half, by a full and perfect blue. Respecting the increased duration of the colour, I have found that when the atmosphere is sufficiently favourable to allow a power of sixty diameters being employed, with a 3-inch object-glass, the green effect is seen at that part of the sun's limb in contact with the horizon, even when one-half the sun is still unset, and of course from then till final disappearance.

The different colours seen, together with the order of their appearance, are suggestive of the prismatic action of the atmosphere as the cause of their production, and the interception of the horizon or the cloud as the cause of their separation.

Assuming the correctness of this view, it becomes evident that an artificial horizon would prove equally efficacious in separating the coloured bands, and also that if employed during an inspection of the sun's lower limb the least refrangible end of the spectrum would be disclosed. Accordingly I introduced into an eyepiece of my telescope a blackened disc of metallic copper, having a slit cut in it of about the one hundred and fiftieth of an inch in width, and proceeded to make an observation, in July, when the sun was about one-half of its meridian height. The blinding glare, however, of that portion of the sun seen through the slit rendered the observation futile. By projecting a large image of the sun into a darkened room, I was enabled to get the whole of the spectrum produced by the prismatic action of the atmosphere in a very satisfactory manner. In this case a semicircular diaphragm was used, so placed that its straight edge divided the field of view into equal parts, from one of which it obscured the light. The diaphragm was placed as before in the focus of the eyepiece, and by rotating it every portion of the sun's limb could be in turn examined, and that too in the centre of the field, so as to be equally subjected to the minimum of the peculiarities of the instrument. When the sun's lower limb was allowed to descend into the field of view the first rays were intensely red. After a momentary duration they gave place in succession to orange, yellow, and green, which were then lost in the ordinary refulgence of the sun. The upper limb gave green, blue, and finally purple, which latter colour I have thus far never seen upon the natural horizon. It should be remarked that the colours seen were vivid and unmistakable, and each one of them easily detained at will, or the whole phenomenon recalled, by the adjusting screws of the instrument. I apprehend that the results here given sufficiently prove that atmo-

spheric refraction is the cause of the coloured rays seen at the moment of the sun's departure below the horizon. I have, however, thought it worth while to examine the light proceeding from the moon's limb by the aid of the artificial horizon, and of course by direct observation. The results were decisive and satisfactory, the spectral colours being easily observed. The green effect I have also frequently seen on the departure of the moon beneath the edge of a dark and well-defined bank of clouds. Telescopic aid has, however, in every instance been required.

The rapid changes in colour observable in the case of almost any large fixed star at an elevation of twenty or thirty degrees above the horizon, and which changes vary between red, green, and blue, may I think be fairly attributed to the same cause as the colour in the sun's final ray. Particles of dust floating in the air act, I apprehend, for the moment, in the capacity of diaphragm or horizon, and thus enable the eye to perceive, even in the light of the stars, the prismatic action of our atmosphere.

Ordinary Meeting, October 21st, 1873.

EDWARD SCHUNCK, Ph.D., F.R.S., F.C.S., Vice-President, in the Chair.

W. BOYD DAWKINS, F.R.S., exhibited a fragment of a post struck by lightning, on 2nd June, 1873. It formed one of three, about 8 feet high and 15 feet apart, in the garden of 11, Norma Road, Rusholme, and stood under a cherry tree, of which the stem was 10 feet away. It was completely shattered, fragments being driven as far as the walls of the house, 25 yards off, and the downward direction of the loose splinters implied that the explosive force was exerted from below upwards, instead of from above downwards. People in the Dickenson Road observed what they termed a "thunderbolt" fall, as they thought, on the house, and some of the inhabitants describe it as a flame of light followed immediately by a crash of thunder. It is very probable that the explosion was produced by an electric current passing from the earth upwards, and not *vice versa*.

Professor REYNOLDS attributed the shattering of the post to the explosive or repulsive action of an electrical discharge of unusual intensity.

Mr. BAXENDELL thought it was most probably due to the sudden conversion of a portion of the moisture in the post into steam of high tension by the heating action of the electrical discharge, and mentioned instances in which condensed vapour was said to have been seen rising from trees immediately after they had been struck by lightning.

"On the Relative Work spent in Friction in giving Rotation to Shot from Guns Rifled with an Increasing and a Uniform Twist," by OSBORNE REYNOLDS, M.A., Professor of Engineering, Owens College, Manchester, and Fellow of Queens' College, Cambridge.

The object of this paper is to show that the friction between the studs and the grooves necessary to give rotation to the shot consumes more work with an increasing than with a uniform twist; and that in the case of grooves which develop into parabolas, such as those used in the Woolwich guns, the waste from this cause is double what it would be if the twist was uniform. This is important, for, although the magnitude of this waste does not appear as yet to have been the subject of direct inquiry, it will be seen that with the plane grooves it amounts to more than 1 per cent of the whole energy of the shot, and, consequently, with the parabolic grooves it will amount to 2 per cent of the energy of the shot; that is, to say the least, important as regards the effect of the discharge; and when we consider that all the work spent in friction is spent in destroying the gun and the shot, we see that it becomes a matter of the very greatest importance whether the gun spends 1 or 2 per cent of its power on self-destruction.

MR. BAXENDELL read the following extract from a letter he had received from the President:—"You will see that

I have put a little drying apparatus to the short limb on my syphon barometer. I believe that a long open tube attached to the short end by a bit of india-rubber tube will do just as well. This I am going to try, and also to exclude the air more perfectly than I find it is in the instrument at the Rooms. The principal fear was that the sulphuric acid would slowly act on the mercury. I think the barometer has been put up long enough to decide this, and I feel convinced that the plan will succeed.

NOTICES OF BOOKS.

Chemistianity (Popular Knowledge of Chemistry); a Poem: also an Oratorical Verse on each known Chemical Element in the Universe, giving Description, Properties, Sources, Preparation, and Chief Uses, arranged for Familiar or Memory Reading. By J. CARRINGTON SELLARS, F.C.S. Published by the Author (at his Office), Ferry Buildings, Birkenhead.

THIS is, without exception, the most remarkable book of the season. Its title—water-marked on every leaf,—its style, its terminology, its probable design, must alike puzzle the unfortunate critic, who in addition, finds himself defied in such passages as the following:—

"Waste-paper set-trap writers shall daunt me not;
The greased feather of my good intents
Shall repel their assafoetidal script
As freezing water from Muscovy duck."

In place of the "Muscovy duck," we fear that a more familiar bird may possibly be suggested to the mind of the reader.

The work consists of a "proemium," treating of a promiscuous assemblage of topics; a "prologue"; a description of the elements in oratorical verse, forming the main body of the book; and an appendix, containing a proposal for an entirely new system of chemical nomenclature. Novel terminology is, indeed, the author's forte. Thus, where chemists would speak of "chemical action" or "reaction," the Chemistian uses the word "goception," derived, as he kindly informs us, "from 'gang,' to pass, and 'præcipio,' to command." Then we have "floral" and "effloral" used as synonyms, respectively, for "mineral" and "organic." Copper is described as the "siamatic bond metal." Last, but not least, we instance "chemistianity" itself. Let us pause, however, before censuring the author for the use of such terms. If he has sinned, he is not alone. He may plead the example of men who, unable or unwilling to enrich science with new facts, new methods, or new generalisations, have earned fame, influence, and professorial chairs by the easier process of translating old doctrines into the terminology of the hour. If paradoxes and neologisms form the royal road to scientific eminence, it would be unfair to shut it against Mr. Sellars.

In the "proemium" the author exclaims:—

"Oh! would that the writers of systems
Themselves would write in some approved system,
Express their facts and views in arid language,
With truth, similes, and impressiveness:
Then there would be less obscurity
And more learning, yielding hornpipe joys through Earth."

Let us make few selections to show the author's approved system:—

"Therefore a human being may be said to be on certain subjects—simple, knowledgeable, subearth-willed, high-witted or with godly lore endowed. One division of the condition of a molecule being might (diffidently) be imagined as that of clarified godly lore."

Here is a portion of a Chemistian song:—

"Chemistian lore should be
Well known on land and sea
To sow the seed of chemistry,
So heigh, so ho, so hee.
Blart quacks will lose their say,
Labour have its due day,
Capital worked in equity,
So hee, so ho, so heigh."

Miss Basic Merit's foe,
Trade-fraud, we'll plunge in woe,
And urge Commercial Honesty,
So heigh, so hee, so ho."

We were not aware that Merit was "Basic" rather than acid, and that it, or rather she, was a young lady. Elsewhere we read:—

"One toned word, like an old familiar tune,
Will suffice to cant-er a rhyming coon."
"Thus marl-peat labour youth, with practical wit,
Tongue him with a Factor's queries and quips."
"By invention of cheap Aqua Blaster,
Which, started, will explosively gocept
When gocepted under Wheeler Blowdome."

From these and similar specimens, which might be greatly multiplied, we are forced to own that, however valuable the truths which the author seeks to convey, his mode of expression is not the most felicitous. It would be interesting to put this volume into the hands of some intelligent person totally unacquainted with chemistry, and to observe what notion of the science he would obtain from its perusal.

The "Oratorical Verse" contains little which is not correct in fact; still it would be difficult to find any information here which is not given more clearly and intelligibly in works easy of access. Hence we fail to see the *raison d'être* of the volume before us. Profit, we are bound to admit, cannot have been the author's motive for appearing in print. He may, possibly, be suffering from the effects of a certain book of which we have heard it said that, when the chemical student has done with it, he may hand it over to his sister or his sweetheart as a collection of crochet patterns.

Mr. Sellars concludes his work with a proposal for a system of "alphabetical composition names" for the chemical elements and "their mineral (floral) compounds." Hydrogen, for instance, is to be called "abgen," to be pronounced *abb*; water becomes DiAbBe; boracic acid is TriAbAmtriBe; chloride of barium is diEbKe. Surely this proposal will commend itself to a certain section of the "Chemistian" world!

MISCELLANEOUS.

Iron in Tea.—Mr. Alfred Bird, of Worcester Street, sends a letter to the *Birmingham Daily Post* on this subject. He says—"In your report of yesterday's proceedings at the Police Court you make me say that 'the magnetic oxide was natural to tea.' What I said was 'that the magnetic oxide of iron exists naturally in the soil in which the tea plant grows,' in proof of which I stated that I had separated from the magnetic oxide of iron (found in the tea) particles of mica and quartz, the inference being 'that, as magnetic oxide of iron forms part of the soil of China, it would rise with the dust of the country, and, coming in contact with the damp leaves, would adhere to them when they are dried, and thus make the dried tea leaves stick to the magnet as if there were iron-filings mixed up amongst them.' I also stated that, not having any of the actual soil of China to examine for magnetic oxide of iron, it occurred to me to try if the dried leaves of plants grown in this country would be attracted by the magnet. Accordingly, I dried 100 grains of French bean leaves, grown in my own garden in the Bristol Road, and, to my great surprise, I found that particles of the leaves were attracted by the magnet, exactly like tea leaves. Now, as it was too absurd to suppose that the French bean leaves had iron-filings sticking to them, I carefully separated the broken leaves from the substance to which they adhered, and found that it was magnetic oxide of iron, the quantity in 100 grains of the bean leaves being 0.2 of a grain. The question then arose, 'Where did the magnetic oxide of iron come from?' To answer this, I dried a few ounces of the black mould of the garden, and, having searched it with the magnet, I attracted out abundance of the magnetic oxide of iron."

THE CHEMICAL NEWS.

VOL. XXVIII. No. 730.

PRELIMINARY INVESTIGATION OF THE FLUORESCENT AND ABSORPTIVE SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON Ph.D.,

(Continued from p. 246).

Uranic Phosphates.

THE salts of this class which we have examined are the following:—

Mono-uranic phosphate,	$U_2O_3 \cdot 2HOPO_5 + 3HO$
Di-uranic phosphate,	$2(U_2O_3) \cdot HO \cdot PO_5 + 3HO$
Di-uranic phosphate hexahydrate,	$2(U_2O_3) \cdot HOPO_5 + 6HO$
Di-uranic phosphate octohydrate,	$2(U_2O_3) \cdot HOPO_5 + 8HO$
Uranic pyrophosphate,	$2(U_2O_3) \cdot PO_5$
Calcio-uranic phosphate,	$CaO \cdot 2(U_2O_3) \cdot PO_5 + 8HO$
Cupro-uranic phosphate,	$CuO \cdot 2(U_2O_3) \cdot PO_5 + 8HO$

The phosphates, like the arseniates, show a remarkable fixity of spectrum, so that, with the exception of the first, all these compounds show the same spectrum of fluorescence. With regard to their absorptive action, a little more variation is manifested.

Mono-Uranic Phosphate, $U_2O_3 \cdot 2HO \cdot PO_5 + 3HO$.—This salt was formed by dissolving uranic hydrate in glacial phosphoric acid. The solution was evaporated in a desiccator until it attained a gelatinous consistency; in this

FIG. 15.

Phosphates.

FIG. 16.

Phosphates.

state it remained for weeks without crystallising. A portion was then transferred to a small specimen-bottle for examination, when it soon began to crystallise in an almost solid mass. Crystallisation also began in the larger quantity, where it had been disturbed, and soon (in a few days) pervaded it also. The material thus formed was

* Communicated by President Morton.

opaque, of a rich green colour, and very brilliant fluorescence. Its spectrum, shown at 1 of Fig. 15, consisted of very broad bands, leaving only narrow dark spaces between them. The material in its gelatinous state, and also the dilute solution, fluoresced, and gave a spectrum in which all the bands were displaced downwards in the spectrum, and are more rounded in character; this spectrum is shown at 2 of Fig. 15. The absorption spectra in these two cases are also well marked, and are given in Fig. 16—1 being that of the solid salt, and 2 of the solution. Both salt and solution held an excess of phosphoric acid.

The various di-uranic and double phosphates already named yield the same fluorescent spectrum, with no difference but a variation in brightness, and this spectrum is shown at 3 of Fig. 15. It so happened that the first specimen examined was one of di-uranic phosphate prepared in the usual way, which gave a double spectrum, as shown at 8 of Fig. 1. Of this, the upper and fainter series of bands corresponds with the above general di-uranic spectrum, while the other, which disappears on drying, no doubt belongs to some hydrate which we have as yet been unable to identify.

The absorption spectra of these salts present a considerable variety of forms. That of the mixed hydrates just mentioned is shown in 8 of Fig. 1, that of the calcio salt at 9 of the same figure, and that of the di-uranic phosphate at 3 of Fig. 16. We have obtained others, but have not yet determined the hydration of the specimens yielding them. It seems likely that these may afford a means of distinguishing some of these salts where their fluorescent spectra are identical.

Sulphates.

The general rule, that bases of the formula U_2O_3 require 3 equivalents of a monobasic acid to form neutral salts, is conspicuously violated by the element uranium, and it was this peculiarity in the constitution of uranium salts which prompted Peligot's assumption of the so-called uranyl theory: thus, neutral uranic sulphate has the composition $U_2O_3 \cdot SO_3 + 3HO$, or, according to Peligot, $(U_2O_2)OSO_3 + 3HO$. This salt is easily obtained by acting on uranic nitrate with concentrated sulphuric acid, or by treating uranic oxide with strong sulphuric acid, and in either case expelling the excess of acid by raising the temperature to about $300^\circ C$. The mass is then dissolved in water, and the solution evaporated to the consistency of a syrup; after standing for some time, small lemon-yellow crystals form, which may easily be separated from the mother-liquid. As thus obtained, the salt, according to the best authorities, contains 3 equivalents of water, 2 molecules of which are driven off in a current of dry air at $100^\circ C$., but the third molecule is given up only on heating to about $300^\circ C$. In this anhydrous state, the great affinity of the sulphate for water is noticeable; each drop as it strikes the mass hisses, and is converted into steam. On dissolving the neutral salt in strong sulphuric acid, and crystallising by spontaneous evaporation, an acid salt, $U_2O_3 \cdot SO_3 + HOSO_3$, is obtained. This uranic disulphate forms small needles grouped in warty concretions, and is of a much greener hue than the neutral sulphate. As will appear below, the spectrum of

the salt is quite different from that of the neutral one.

A trisulphate is described by Berzelius, but its existence is denied by Peligot. Its formula, according to the uranyl theory, would be $(U_2O_2)O_3 \cdot SO_3$, which is highly improbable. At present writing, attempts to obtain a trisulphate with a definite spectrum have been unsuccessful

Ordway (*Am. Journ. Sci.*, [2], xxvi., 208, 1858) obtained a tribasic sulphate, $3\text{UO}_3 \cdot \text{SO}_3$, by treating a solution of the normal salt with baric carbonate; this compound, as well as the minerals johannite, zipperite, uranochalcite, medjidite, voghanite, and uraconite (Dana)—different varieties of hydrous uranic sulphate,—have not as yet been examined.

The optical study of the uranic sulphate was attended at the outset by great difficulties, arising from the fact that, after several specimens had been studied which gave the same spectrum—that, namely, shown at 1 of Fig. 17,—others, prepared under what were supposed to be identical conditions, showed such spectra as from previous experience we had reason to believe indicated the existence of a mixture (see 3, Fig. 17). After seeking in vain for any impurity, it became at last evident that these mixed spectra resulted from the presence of the salt in two states of hydration, which depended upon very slight variations in their mode of crystallisation and subsequent exposure. It

other set to be unlike those of the normal salt (see 3 of Fig. 17).

We have as yet been unable to isolate the substance giving these bands, but we have no doubt that they belong to the bihydrate of the uranic sulphate. By continuing to heat the substance in which this double spectrum has been developed we can reduce the strength of the bands belonging to this unisolated substance, and relatively strengthen those of the other, a small amount of water being at the same time expelled; but we cannot apparently reduce the mixture to the condition of the mono-hydrate alone. Thus a sample which had lost 5.7 by being heated suddenly to 100° , and refused to lose more at that temperature, by heating to 150°C . lost 0.5 per cent more, and then maintained a constant weight. The spectrum in both cases being of the same duplex character, and differing only in the relative strength of the two sets of bands.

If this same salt in a normal state is placed suddenly in an oven at 150° it will lose about 8.7 per cent of water, but will again still show the same double spectrum, but with a loss of brilliancy in fluorescence. It therefore seems highly probable that in this case the salt has in part been reduced to an anhydrous condition in which it has no fluorescence.

The formation of certain of these hydrates seems to depend upon the combined action of heat and moisture due to the suddenness of the heat, which in driving out the water from part of the salt bathes another part in its hot vapour. We have made some experiments in the direction which this suggests, but as yet without reaching a decided result. There are, however, some analogous cases to which we would call attention. Thus the blue hydrate of cupric oxide changes to black anhydrate by a heat of 100° when diffused in water; so the ferric hydrate. Again, a solution of $\text{ClO} \cdot \text{SO}_3 + 3\text{H}_2\text{O}$ yields, on heating, crystalline flakes of $2(\text{ClOSO}_3 + 3\text{H}_2\text{O})$, or abandons half its water. From what has been done, however, we think that we may, without risk of error, assume that the neutral uranic sulphate forms three hydrates with one, two, and three equivalents of water respectively, and that each of these has a distinct and characteristic spectrum.

The uranic disulphate gives a spectrum in which the bands are much less defined than are those of the normal

salt, and are also less unlike in the abruptness with which they shade off on their upper and lower edges. The positions of their centres or brightest parts are given in the following table:—

Spectrum of Uranic Disulphate.

Bands.	1.	2.	3.	4.	5.	6.	7.	8.
	33.2	40.8	48.4	57.6	66.8	76.4	86.0	94.0

If this salt is dried over sulphuric acid it has its fluorescence somewhat reduced, and the position of its bands is elevated in the spectrum, as the following table will show:—

Spectrum of Dried Uranic Disulphate.

Bands.	1.	2.	3.	4.	5.	6.	7.	8.
	33.2	41.2	49.2	58.5	68.0	78.0	87.6	96.8

In solution the above-mentioned salts fluoresce with moderate brightness, and give banded spectra, the position of whose lines does not seem to differ from that of the solid salt. If a solution is made in strong sulphuric acid the fluorescence is very bright, but the position of the bands seems to be unchanged. In these solutions, however, the bands are in all cases less defined than in the solids.

The absorption-bands of the neutral and acid sulphates are shown in 1 and 2 of Fig. 18 respectively, and in 3 we find the bands of the solution of either of these, or, indeed, of any other uranic sulphate which we have yet examined.

FIG. 17.

Uranic Sulphate.

FIG. 18.

Uranic Sulphates.

required, however, a long course of experiments to develop these facts, and to fix even some of these conditions, and others yet await further investigations.

To put the matter in its most concise shape, we will here briefly state the results so far obtained. When the uranic sulphate crystallises from a cold solution by evaporation in the air, or sometimes by cooling from a hot solution, it takes up 3 atoms of water, and yields the spectrum shown at 1, Fig. 17, which may be regarded as its normal spectrum. The presence of a moderate excess of acid does not seem to effect this, though it has a decided influence on the subsequent behaviour of the salt.

If this salt is exposed to the air until adherent moisture has been carried off, and is then slowly dried, at first below and then at 100°C ., it will lose 2 atoms of water and pass to the condition of the mono-hydrated salt. It then yields such a spectrum as is shown at 2 of Fig. 17. If, however, the drying is carried on rapidly, as, for example, by placing the moist salt in a hot-water oven already at 100°C ., evaporating the solution nearly to dryness on the water-bath, or occasionally even by drying over sulphuric acid, an amount of water is lost varying between 4.9 per cent and 5.7 per cent, and a double spectrum is developed, in which one set of bands seems to correspond with those of the mono-hydrate, and the

It would seem with the sulphates, as with the acetates, that all are reduced to the same condition when in solution, and that this condition seems to be that of the neutral acetate. There is, however, this decided want of parallelism in the two cases, that, whereas an excess of acetic acid is necessary to bring out the spectrum of the acetates, an excess of sulphuric acid seems to have no effect. The fluorescence, also, of these solutions is unaffected by an excess of acid, or, rather, is very much brighter where pure sulphuric acid is the solvent than in the aqueous solution.

(To be continued).

"IRON FILINGS" IN TEA.

By W. MATTIEU WILLIAMS, F.C.S.

I HAVE watched the progress of the tea controversy and the other public performances of the public analysts with considerable interest; it might have been with amusement, but for the melancholy degradation of chemical science which they involve. Among the absurdities and exaggerations which for some years past have been so industrially trumpeted forth by the pseudo-chemists who trade upon the adulteration panic and consequent demand for chemical certificates of purity, the continually repeated statements concerning the use of iron filings as a fraudulent adulterant of tea takes a prominent place.

I need scarcely remark that, in order to form such an adulterant, the quantity added must be sufficiently great to render its addition commercially profitable to an extent commensurate with the trouble involved. Now the gentlemen who, since the passing of the Adulteration Act, have by some kind of inspiration suddenly become full-blown chemists, have certified to wilful adulteration of tea with iron filings, and have obtained convictions on such certificates, when, according to their own statement, the quantity contained has not exceeded *five per cent* in the cheapest qualities of tea. Now the price of such tea to the Chinaman tea-grower, who is supposed to add these iron filings, is about fourpence to sixpence per pound; and we are asked to believe that he will fraudulently deteriorate the market value of his commodity for the sake of this additional 1-20th of weight. Supposing that he could obtain his iron filings at twopence per pound, his total gain would thus be about 1-10th of a penny per lb.

But can he obtain such iron filings in the quantity required at such a price? A little reflection or a few figures will render it evident that he cannot, and that such adulteration is utterly impossible.

I find, by reference to the *Grocer* of November 8th, that the total deliveries of tea in the Port of London during the first ten months of 1872 was 142,429,337 lbs., and during the corresponding period of 1873 139,092,409 lbs. Of this, about 84 millions of pounds in 1873, and 10 millions of pounds in 1872, were green, the rest black. This gives, in round numbers, about 160 millions of pounds of black tea per annum, of which above 140 millions come from China. As the Russians are greater tea drinkers than ourselves—the Americans and British colonists are at least equally addicted to the beverage, and other nations consume some quantity—the total exports from China may be safely estimated to reach 400 or 500 millions of pounds. Let us take the smaller figure, and, adopting the more moderate statements of the adulteration panic mongers, suppose that only one-fourth of this is adulterated, to the extent of 5 per cent, with iron filings. How much will be required? Just 5 millions of pounds per annum. Now it must be remembered the *coarse* filings could not possibly be used; they would show themselves at once to the naked eye as rusty lumps, and would shake down to the bottom of the chest; neither could borings, nor turnings, nor plane-shavings be used. Nothing but *fine* filings will answer the supposed purpose. I venture to assert that if the China tea-growers were to put the whole world under contribution for their supposed

supply of fine iron filings, this quantity could not be obtained. Let anyone who doubts this borrow a blacksmith's vice, a fine file, and a piece of soft-iron, then take off his coat and try how much labour will be required to produce a single ounce of filings, and also bear in mind that fine files are but very little used in the manufacture of iron. As the price of a commodity rises when the demand exceeds the supply, the Chinaman would have to pay far more for his adulterant than for the leaves to be adulterated. As Chinese tea-growers are not public analysts, we have no right to suppose that they would perpetrate any such foolishness.

The investigations recently made by Mr. Alfred Bird, of Birmingham, show that the iron found in tea leaves is not in the metallic state, but in the condition of oxide, and he confirms the conclusions of Zöller, quoted by Mr. J. A. Wanklyn in the *CHEMICAL NEWS*, of October 10, viz., that compounds of iron naturally exist in genuine tea.

It appears, however, that the ash of many samples of *black* tea contains more iron than naturally belongs to the plant, and accepting Mr. Bird's statement that this exists in the leaf as oxide mixed with small siliceous and micaceous particles, I think we may find a reasonable explanation of its presence without adopting the puerile theory of the adulteration maniac, who in his endeavour to prove that everybody who buys or sells anything is a swindler has at once assumed the impossible addition of iron filings as a make-weight.

In the first place we must remember that the commodity in demand is *black* tea, and that ordinary leaves dried in an ordinary manner are not black but brown. Tea leaves, however, contain a large quantity of tannin, a portion of which is, when heated in the leaves, readily convertible into gallo-tannic or tannic acid. Thus a sample of tea rich in iron would, when heated in the drying process, become by the combination of this tannic acid with the iron it contains, much darker than ordinary leaves or than other teas grown upon less ferruginous soils, and containing less iron.

This being the case, and a commercial demand for *black* tea having become established, the tea grower would naturally seek to improve the colour of his tea, especially of those samples naturally poor in iron, and a ready mode of doing this is offered by stirring in among the leaves while drying a small additional dose of oxide of iron, if he can find an oxide in such a form that it will spread over the surface of the leaf as a thin film. Now it happens that the Chinaman has lying under his feet an abundance of material admirably adapted for this purpose, viz., red hæmatite, some varieties of which are as soft and unctuous as graphite, and will spread over his tea leaves exactly in the manner required. The micaceous and siliceous particles found by Mr. Bird are just what should be found in addition to oxide of iron, if such hæmatite were used.

The film of oxide thus easily applied and subjected to the action of the exuding and decomposing extractive matter of the heated leaves would form the desired black dye or "facing."

The knotty question of whether this is or is not an adulteration is one that I leave to lawyers to decide, or for those debating societies that discuss such interesting questions as whether an umbrella is an article of dress. If it is an adulteration, and as already admitted, is not at all injurious to health, then all other operations of dyeing are also adulterations, for the other dyes, like the Chinaman, add certain impurities to the silk, wool, or cotton, in order to alter their natural appearance, and give them the false facing which their customers demand, but with this difference, if I am right in the above explanation, that in darkening tea nothing more is done but to increase the proportion of one of its natural ingredients, and to intensify its natural colour, while in the dyeing of silk, cotton, or wool, ingredients are added which are quite foreign and unnatural, and the natural colour of the substance is altogether falsified.

ON THE
ACTION OF BROMINE ON THE WATER-SALTS
OF SUCCINIC, MALIC, MALEIC, AND
PYRO-CITRIC ACIDS,

CRITICALLY EXAMINED AND INTERPRETED FROM THE
STANDPOINT OF THE "TYPO-NUCLEUS" THEORY.

By OTTO RICHTER, Ph.D.

(Concluded from p. 248).

PART II.

On the Principal Molecular Changes that attend the Action
of Bromine on the Water-Salts of Pyro-Citric Acid.

When the three isomeric modifications of pyro-citrate of
water are treated with bromine, the resulting dibrominated
meta water-salts are expressed by the collective formula—

In this process the bromine is understood to act in accord-
ance with the second method, so that the first stage will
be marked by the direct union of 2 mols. of bromine with
the complex carbon adjunct.

In the next stage 2 mols. of water suffer decomposition,
their oxygen serving to oxidise the formous acid principal,
while their hydrogen, by reacting upon the dibrominated
carbon adjunct, gives rise to a molecule of hydrobromic
acid, which, by transposing with the colligated alcohol,
completes the formation of the new compound.

The reader, by taking his cue from the behaviour of the
ortho-succinate under similar circumstances, will not be
slow to perceive that the dibrominated derivative of the
ortho-pyro-tartrate, which is the next upper homologue
of the succinate, ought to be expressed by the formula—

but although Lagermann and others have tried to obtain
this compound by the usual method, they do not seem to
have arrived at satisfactory results.

In connection with this subject a singular fact has been
brought to light, which is, that under the influence of
sodium amalgam these three varieties of meta-dibromo-
pyro-tartrate agree with their parent molecules, the three
varieties of pyro-citrate, in producing but a single variety
of ortho-pyro-tartrate, instead of the three which are
indicated by theory. In order to account for this dis-
crepancy, I proceed upon the hypothesis that the three
varieties of meta-pyro-tartrate are actually formed at the
commencement, but that in the existing conditions they
are speedily made to merge into the β variety of the ortho-
pyro-tartrate.

It is meet that I should now advert to a very interesting
series of transformations which certain descendants of the
three varieties of meta-dibromo-pyro-tartrate are apt to

experience under the influence of certain chemical reagents.
When the salts of these three varieties are boiled with
water, carbonic acid is given off, and two varieties of
dibromo-butyrate are left behind. Their formula—

is based upon the following train of reasoning:—

In the first stage, 2 mols. of water yield up their oxygen
to the formic acid ally; while their hydrogen, by reacting
upon the bromo-hydrocarbon adjunct, gives rise to a
molecule of hydrobromic acid, whose immediate union
with a molecule of formen, &c., completes the formation
of the compound—

This meta water-salt soon resolves itself, in the next stage,
into 2 mols. of water which are liberated, and the ortho
water-salt—

which, by the loss of 2 mols. of carbonic acid, becomes
finally converted into the dibromo-butyrate, as formulated
above.

It is at this point that the interesting series of meta-
morphoses commences, to which allusion has just been
made, but for the proper comprehension of which I require
to submit first of all the analysis of a kindred and more
familiar, but as yet perfectly unintelligible, series of
reactions. The case selected for illustration and com-
parison refers to the characteristic deportment of the
dibromide of ethylen on its being subjected to the alternate
influence of hydrate of potash and bromine. Now the
molecular changes attending the successive stages of this
curious reaction may be described as follows:—

In the first stage, the dibromide of ethylen—

transposes with the hydrate of potash, with production of
the compound—

and bromide of potassium, under the influence of which
the former molecule is speedily made to resolve itself into
2 mols. of water and the body—

In contact with 2 mols. of bromine, this latter becomes
then changed into the compound—

which, with the aid of a second molecule of hydrate of
potash, becomes quickly reduced to the body—

SYNOPTICAL ARRANGEMENT OF CHEMICAL FORMULÆ, COMPRISING THE BROMINATED DERIVATIVES OBTAINED BY THE
ALTERNATE ACTION OF HYDRATE OF POTASH AND BROMINE ON THE DIBROMO-BUTYRATE OF WATER.

Dibromo-butyrate—

Tribromo-butyrate—

Tetrabromo-butyrate—

Bromo-crotonate—

Dibromo-crotonate—

Tribromo-crotonate—

In contact with a second pair of bromine molecules, this latter becomes then changed into the compound—

which, with the aid of a third molecule of hydrate of potash becomes finally transformed into the body—

By applying the preceding train of reasoning to the dibromide of allylen, which in the dibromo-butyrate is made to play the part of a halogen adjunct, the reader will not find it difficult to interpret the molecular changes which ensue on the dibromo-butyrate being subjected to a similar treatment. It will, therefore, suffice to append a list of the chief transition products with which, in the absence of the customary winding up, this paper is perhaps rather abruptly brought to a close.

PROCEEDINGS OF SOCIETIES.

GLASGOW PHILOSOPHICAL SOCIETY: (CHEMICAL SECTION).

THE first meeting of the session of the Chemical Section of the Philosophical Society of Glasgow was held on the evening of Monday, November 10th, when Dr. William Wallace, F.R.S.E., delivered the opening address as retiring President.

After a few introductory remarks, Dr. Wallace spoke with some detail on the operation of the Adulteration Act, and the difficulties attending it so that convictions might be obtained in accordance with its spirit. He specially referred to milk and tea among the articles of food that are subjected to adulteration. The only cure for the anomaly of retailers of tea being subjected to the hardship of being severely fined for selling adulterated tea, though they were perfectly innocent of the fact that it was adulterated, would be to have each cargo of tea, as it arrives at port, examined by Government officials, who should have power to order the destruction of all tea which had been mixed with adventitious matter. Dr. Wallace considered that there could be no doubt that the Adulteration Act would greatly increase the number of professional chemists in this country. Already some of the gentlemen appointed as Analysts had exercised their vocation, not only in testing the samples submitted to them, but also in adding important facts to our knowledge regarding certain articles of food. He strongly urged the desirability of appointing, as Analysts under the Act, competent and experienced chemists having reputations to support, and making it worth their while to give attention to their duties, by giving them fixed incomes in addition to moderate fees.

The prevention of smoke next received some notice from Dr. Wallace, and the operation of the law relating to that subject was shown to be somewhat anomalous in Glasgow, inasmuch as a person might erect a hundred puddling furnaces within the city, which might give off dense volumes of the blackest smoke day and night, without the owner being interfered with, for the law could not touch him; but if the thousandth part of the smoke were emitted from a badly-fixed boiler, the myrmidons of the law would pounce upon the owner at once.

Dr. Wallace dwelt at considerable length upon the chemical questions involved in the disposal of the sewage of large towns, and the conservation of the purity of rivers. There was probably no great town or city in the three kingdoms where the whole question of the disposal of the sewage had been so thoroughly discussed, or so perfectly understood, as in Glasgow, and there was perhaps none in which so little had been done. The local sewage literature was of great extent and value, but the citizens had hitherto been content to look on and witness the experiments conducted elsewhere, sometimes at enormous expense, and the failures that had almost invariably attended the experiments. There were local gentlemen, high in office, who were in favour of the great Bateman and Bazalgette scheme of pumping and conveying the Glasgow sewage to the sands on the Ayrshire coast, for the purpose of irrigation, at a cost of something like £2,000,000; but he sincerely hoped that those gentlemen would study the subject further, and see for themselves the results of sewage irrigation elsewhere. For the Glasgow sewage an area of 25,000 acres, or nearly forty square miles, would be required for the Glasgow sewage if irrigation were to be resorted to.

After speaking of the various systems of sewage filtration and so-called purification—General Scott's, the A B C, and that by the use of peat charcoal, as practised at Bradford—Dr. Wallace said that a revised Pollution of Rivers Act would doubtless be passed next session, and that not unlikely it would be made applicable to Scotland as well as to England, in which manufacturers would be brought under a very stringent law; but, as long as the water-closet sewage was discharged into rivers, it would be ridiculous to impose penalties upon manufacturers for adding their comparatively trifling contribution of polluting ingredients. Dr. Wallace concluded his address by making some very practical remarks regarding the endowment of scientific research, a subject to which renewed interest had been imparted by the address of Professor Williamson as President of the British Association at its recent meeting at Bradford. He said it was disgraceful that in Glasgow, a city which owed so much of her wealth to chemical manufactures, there was no professor of technology, and that even the chair of chemistry was so miserably endowed that its occupant—one of the ablest and most industrious of modern chemists—was obliged to eke out the means of subsistence by commercial work which, though important enough in itself, might be performed equally well by men of far inferior talent and originality.

Speaking of analytical work, he said that, in this country especially, it had become an important branch of the profession, and that it had of late years attained a scientific precision which it never before possessed. It was not uncommon for analyses to be made for commercial purposes, and for a comparatively trifling fee, with greater skill and a higher degree of accuracy than was exhibited in a large proportion of the researches published in scientific journals; and it often happened that a chemist brought up in what might be called a strictly scientific laboratory was totally incapable of undertaking the simplest analyses with results that were of any practical use. Such knowledge, like every other kind that was valuable, was only to be acquired by hard work and great practice, but that fact made it impossible for an analyst having a large and engrossing business to devote any portion of his time or talents to the higher branches of chemical study. Other sub-divisions of chemical science led to the

same exclusiveness of thought and narrowing of observation and it was just to prevent the evil results that would naturally follow that a Society such as the Chemical Section was valuable in bringing together men who studied different branches of the science, and enabled them to communicate their ideas and knowledge to the mutual benefit of all.

The address was listened to most attentively and heartily applauded, and at its conclusion, on the motion of Mr. Mayer, seconded by Mr. John Jex Lang, a cordial vote of thanks was passed to Dr. Wallace. A hope was also expressed that the address would as soon as possible be published *in extenso* in the *Proceedings* of the Philosophical Society.

CORRESPONDENCE.

PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—Every chemist will be pleased with your remarks upon the way in which the Adulteration of Food &c. is being carried into law. I think that it is high time that something be done to stop the sliding of the post of public analyst into unqualified hands. So far as the appointments of analysts have as yet proceeded, they have either fallen upon one lucky individual, or relapsed into the possession of a complete tyro. It is stated that Professor Gardner, of the Polytechnic, is unable to "qualitatively" detect alum in bread for a fee of 10s. 6d., but he can do so "quantitatively" for 5 guineas. I allude to the Shore-ditch case. Will "the learned Professor" kindly explain? He has given his share towards the impression that there ought to be a "Society for the Protection of Tradesmen from Analysts."—I am, &c.,

Og.

[We shall probably give an article in our next issue on the detection of alum in bread.—Ed. C. N.]

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 13, 1873.

Purifier for Coal-Gas, Capable of Serving at the Same Time for Mixing Gases with the Vapours of Liquids.—M. D. Colladon.—Gas requires to be freed from particles of solid matter, naphthalin, coal-tar, ammoniacal salts &c., as well as from gases such as carbonic and sulphurous acids. For washing it vessels have been employed similar to Woolf's bottle, in which the gas traverses water or a suitable solution through a metallic network in the form of bubbles or continuous currents. This arrangement is insufficient for working on a large scale; because the bubbles of gas take a spherical form, and consequently present a minimum of surface for a maximum volume. Further, this method requires a decided increase of pressure, which is inconvenient. Chemical "cascades," in which the gas passes upwards through a fine rain of the washing liquid, act much better,

but require too large a quantity of liquid. Coke-towers (scrubbers) produce a more complete effect, but the action is irregular. The new mechanical washing apparatus has the advantage of producing very powerful action without requiring large dimensions. At Geneva it yields coal-gas, superior both in illuminating power, and in a sanitary point of view. Less purifying matter is also required than on the old system. The same apparatus will doubtless prove useful when it is required to saturate a gas with the vapours of a liquid, e.g., hydrogen with the vapour for petroleum. The system rests on this principle, that the best arrangement either for washing a gas or for saturating it consists in making it strike, in the form of currents as thin as possible, against solid walls kept perpetually moist. The currents are broken against these surfaces, and are prevented from moving on in a straight line. The gaseous particles are thus always kept in a rotatory movement, and are pressed against the moist walls, so that they may either absorb the substance diffused over these walls or may deposit there a part of their own substance, according as it is required to saturate the gas or to wash it.

New Method of Tempering Steel, and Regeneration of Burnt Iron.—M. H. Caron.—A piece of steel is generally tempered, and then re-heated more or less according to the hardness and the elasticity which it requires to receive. The dry temper, as commonly practised, that is to say, the plunging the red-hot metal into cold water, has the drawback of developing cracks and crevices injurious to its tenacity. Re-heating does not remove these flaws; and subsequently on use these fissures, though invisible at first, increase and terminate in fractures. It has already been discovered that in order to escape from this danger it is preferable to temper the steel a little less hard, and afterwards to re-heat more slightly. The author has succeeded in producing the combined effects of tempering and re-heating in one operation, and of removing as far as possible the chances of flaws. This is done by heating the water into which the red-hot metal is plunged to 55°. Tempering in hot, or even boiling water, modifies soft steel containing two- to four-thousandths of carbon. This process augments its tenacity and elasticity without sensibly altering its softness. The texture is changed and becomes fibrous, even if previously crystalline. The author's method for restoring burnt metal is likewise to plunge it at a red heat into a hot liquid.

Use of Bisulphite of Potassa as Test for Galena in all its Mixtures.—M. E. Jannetaz.—It is sufficient to throw upon coarsely pounded galena a fragment of bisulphate of potash to produce a distinct evolution of sulphuretted hydrogen. If the two bodies are ground together the odour becomes almost insupportable. Bisulphate of potash, kept in fusion for half-an-hour, produces the same effect, perhaps with less intensity. Sulphuric acid, mixed or even heated with galena, does not give rise to a sensible disengagement of sulphuretted hydrogen. Blende gives a sulphydric odour, but less intense. Sulphides of antimony, iron, mercury, and silver give off no sensible odour. Boulangerite, zinkenite, bournonite, and, in general, the sulphides in which lead and sulphur do not form an isolated combination, do not yield their sulphur to the bisulphate of potassa.

On Crystalline Dissociation (Continued); Evaluation and Distribution of Work in Saline Solutions.—MM. Favre and Valson.—The authors here examine the coercive effects produced by some thirty different salts on their solvents. The following are some of the chief results:—(1) All the salts examined, except chloride, bromide, and iodide of ammonium, give contraction. (2) Taking as measure of coercive action the specific contraction represented by—

$$\frac{V-v}{V}$$

(where V is the volume of an equivalent of the salt

and v the increase of volume in the water) the salts, with regard to coercitive energy, may be thus grouped; first group, carbonates and borates; second, sulphates and fluorides; third, chlorides, acetates, and bromides; fourth, iodides. Comparing the metallic radicals we have this other arrangement:—first, aluminium and copper; second, strontium, barium, and calcium; third, sodium and potassium; fourth, ammonium. Sulphate of alumina and carbonate of soda gave the greatest contraction; iodide of ammonium gave the least. (3) In dissolving there are two opposite effects—contraction of the solvent and increase of volume of the salt; the former being generally greater than the latter. (4) The values of d (the densities of "normal," solutions in which an equivalent of the salt is dissolved in 1 litre of water) afford new evidence that each saline radical produces in the solution an increase of density, which is proper to it, and independent of, any other radical with which it may be associated. (5) The negative values of $V-v$ obtained for chloride, bromide, and iodide of ammonium, and the almost *nil* value of $V-v$ for nitrate of ammonium, seem to show that in salt solutions the ammonical salts are in a much more advanced state of dissociation than the other salts studied. The authors next offer some observations which seem to favour the supposition that the constituent elements of salts themselves may experience, in a certain measure, a phenomenon of dissociation more or less advanced, such as occurs, *e.g.*, in the passage of ordinary hydrogen to the state of active hydrogen. We may interpret the phenomenon of coercion by comparing with it the well-known phenomenon of the condensation of gases and liquids by solid bodies. Consider what occurs when CO_2 (for example) is condensed by charcoal. The gas, in condensing to the full, liberates a quantity of heat greater than that which it liberates in solidifying. Moreover, in condensing by successive fractions, the first fraction of gas liberates more heat than the second, the second more than the third, and so on to the last. So that, under the coercitive influence of charcoal, the carbonic acid seems to form layers of decreasing density (starting from the surface of condensation). Something very similar probably occurs when a salt is in the presence of water; the molecular surfaces of the solid, brought to a state of extreme division, acting on the water, and giving it a density superior to that which it has in the liquid state, and even in the solid state.

Researches on the Ancient Fauna of the Island of Rodrigues.—M. Alph. Milne-Edwards.—This island, about three hundred miles E.N.E. from Mauritius, had in the 17th century a rich vegetation and varied fauna; but the animals have almost entirely disappeared, in consequence, direct or indirect, of the destruction of the woods by burning.

Verification of Huyghens's Law of Double Refraction by the Prism Method.—Extract from memoir by M. Abria.—Suppose a bi-refrangent surface in the form of a prism presenting five diedral angles; the axis having a certain direction. If one measures for a particular line, D for example, the index of refraction of each of the rays, bringing the prism into the position of minimum of deviation for the rays, one should find a constant value of the index for one of them, which will be the ordinary ray, and will thus be determined. The prism being in the position of minimum deviation, for the ordinary image, if one measures the angle which the emergent rays form, ordinary and extraordinary, in their exit from the prism; this may then be compared with the result obtained by Huyghens's law. If there is agreement no doubt can remain as to the correctness of this law. The author gives, in a table, the result of eighteen experiments; ten with a prism of spar, and eight with two quartz prisms. The differences are nearly always under $\frac{1}{100}$ th of the quantity measured, thus confirming the law.

Researches on the Action of Substances Termed Antiseptic on Carbonaceous Virus.—M. Davaine.—

(It was stated in a previous note that the virus was destroyed by a temperature varying between 48° and 55°C. , according to the duration of application of the heat.) The antiseptic agents examined are arranged in the following order of power:—Ammonia, silicate of soda, ordinary vinegar and phenic acid, caustic potash, chloride of oxide of sodium, hydrochloric acid, permanganate of potash, chromic acid, sulphuric acid, iodine. The power of ammonia, vinegar, and phenic acid being represented by 100, that of iodine will be represented by 1100.

Studies on Phylloxera. (Continued.)—M. Max Cornu.—The insect attacking the leaves is the same as that attacking the roots, but it is less attracted by the former.

Reproduction of Phylloxera of the Oak.—M. Balbiani.—The reproduction of the apterous generations of phylloxera in summer is by parthenogenesis; but this is not the only way of reproduction of the insect.

Meteorological Observations in a Balloon.—M. Tissandier.—The ascent took place on the 4th ult. about midday, from the gas-works of La Villette. A lower current carried the *aérostat* in the direction E.S.E., but at a height of 700 metres there was a south-west current which carried it to the N.E. The lower had a velocity of 6 to 7 kilometres in the hour, the higher 35 kilometres. The maximum height reached was 2600 metres, where the balloon entered an extensive bank of cumulus. The polarisation of the atmosphere was here much weaker than at the surface of the ground. The hygrometric and thermometric measurements are given. The shadow of the balloon was always visible on the ground. At 1.35 p.m., and at a height of 700 metres, this shadow—projected on a meadow—appeared to be surrounded by a very bright aureole of yellow colour.

New Remarks on the Epidemic Goitre in the Barracks at St. Etienne.—M. Bergeret.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, par Ch. Mène, No. 41, 1873.

Vinous Syrups for the Fabrication of Low Class Wines.—These syrups are special saccharine liquids analogous to the juice of grapes, containing tannin, salts, &c., and colouring matters. It appears that they are to be mixed with the residue of the grapes after the first pressure and pressed again, so as to yield a further quantity of a liquid which may pass for wine. M. Mène thinks that by this system "dangerous and gross falsifications" may be prevented; which are a calamity to the country and to society, because they interfere with and injure not merely health, but (what M. Mène appears to think more important) "business and progress."

Destruction of the Phylloxera and other Parasites of the Vine.—Tessié du Motay waters the vine at its roots with a solution of a soluble alkaline or alkaline hyposulphite. When this solution is judged to have penetrated sufficiently, he waters anew with a solution containing a sufficient quantity of acid phosphate of lime, soda, or potash so that the excess of phosphoric acid may saturate the base of the hyposulphite, and liberate sulphur in the nascent state. In another procedure the same chemist recommends to water with an alkaline or alkaline-earth polysulphide, and subsequently with a sufficient quantity of an alkaline bisulphite to produce the same reaction, the liberation of nascent sulphur.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 251, November, 1873.

Distribution of Potash and Soda in Plants.—M. Eug. Peligot.—This paper is taken from the *Comptes Rendus*, and has been already noticed in our columns.

Böttger's Portable Ink.—The author saturates several sheets of paper with aniline-black, and presses them together into a compact and portable mass. For

writing it is merely necessary to tear off a piece of this paper, and steep it in a little water.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., No. 10, November 6, 1873.

New Fuel.—Pagliari has invented a new combustible to take the place of coal. It consists of—

Distilled petroleum	20 kilos.
Resin	30 "
Coal dust.. ..	40 "
Charcoal dust.. ..	30 "
Saw dust.. ..	6 "
Sulphate of lime	10 "

136

The petroleum is placed in a metal boiler heated by steam, the temperature being gradually raised to 75°. It is constantly stirred, and when the resin is dissolved the steam is shut off, and the other substances are introduced. When the whole is thoroughly incorporated it is run into moulds. Clay may be substituted for the coal. In another formula 25 parts of crude petroleum are substituted for the 20 parts of distilled petroleum. It is announced that the calorific power of this combustible is double or even triple that of coal. (We doubt whether a mixture containing nearly one-fourth its weight of resin, can ever seriously compete with coal even at present prices.)

Revue Scientifique de la France et de l'Etranger,
November 1 and 8, 1873.

These numbers contain no chemical matter.

Gazzetta Chimica Italiana, Anno iii.,
Fascicolo ix., 1873.

Action of Cyanide of Potassium on Bichloroacetic Acid.—D. Amato.—In a former notice the author speaks of a substance of a finely crystalline appearance. Its composition is—

Carbon	41.5
Hydrogen	5.7
Nitrogen	16.0
Oxygen	36.8

100.0

and its formula $C_6H_{10}N_2O_4$. The author treats likewise on the action of cyanide of potassium upon dilute alcohol, and on a new method of preparing allophanic ether.

New Reagent for Iodates.—Egidio Pollacci.—The proposed reagent is very sensitive, and can be applied as well in cases where the iodates are unmixed as where they are associated with iodides. If phosphorus is placed in contact with an aqueous solution of iodate of potassium, the iodine of such salt, however dilute may be the solution, is perfectly reduced. The same reaction occurs with other iodates. The first action is a partial reduction of the iodate, with formation of phosphoric acid and iodide of potassium. Subsequently the phosphoric acid acts upon the iodide as well as upon the iodate, forming phosphate of potash, and iodic and hydriodic acids. Lastly, these two acids being incompatible form water and iodine.

Bulletin de la Societe Chimique de Paris, tome xx., Nos. 6 and 7, October 5, 1873.

Reciprocal Action of Oxalic Acid and of the Polyatomic Alcohols; Application to the Manufacture of Formic Acid.—M. Lorin.—The author has previously pointed out the principal phenomena resulting from the reciprocal action of oxalic acid and glycerin. He finds that the same acid gives identical results with ordinary glycol, octylic glycol, erythrite, mannite, dulcitol, and

quercite. From the first addition of an equivalent of common oxalic acid, the formic acid is almost entirely fixed upon the equivalent of polyatomic alcohol. The physical properties of the alcohol exert an influence upon the stability of the oxalic acid. Water has also an influence contributing to the regular etherification of the oxalic acid and to the constancy of the limit. For the preparation of formic acid, 1.120 kilos. of pure glycerin and 3 kilos. of powdered oxalic acid were placed in a roomy retort. The reaction was kept up by making successive additions of the acid, morning and night, in such quantities that the original level of the mixture was kept up. The retort was cooled a little before each addition. 65.25 kilos. of oxalic acid yielded 42.14 kilos. of formic acid at 54.6 per cent = 23.004 kilos. of pure acid.

Hydrochlorate of Tereben, and on the Isomerism of the Compounds of the Formula $C_{10}H_{16}HCl$.—M. J. Ribau.—The hydrochlorate of tereben consists of—

Carbon	69.58
Hydrogen	9.85
Chlorine	20.57

100.00

It fuses at 125°, and is rapidly decomposed in contact with water.

Solubility of Sulphate of Lead in Acetates.—H. C. Debbits.—The author finds that sulphate of lead is soluble in the acetates of soda, lime, manganese, zinc, nickel, and copper. The acetates of mercury and silver have no such solvent action. The acetate of baryta, at common temperatures, partially converts the sulphate of lead into acetate of lead and sulphate of baryta; the inverse reaction does not take place.

Certain New Sulpho-Salts.—R. Schneider.—The author has examined the sulpho-palladiate of potash and sulpho-palladiate of silver; tetra-platinous sulpho-stannate and tetra-platinous sulpho-platinate.

Artificial Production of Crystalline Fluor-Spar and Sulphate of Baryta.—Th. Scheerer and E. Drechsel.—Fluor-spar has been obtained in octohedral crystals by fusing the amorphous fluoride in the chlorides of calcium, potassium, or sodium, and cooling slowly. The authors have also obtained the fluoride of barium in crystals on evaporating its solution in dilute nitric acid.

Sulphate of Ethylen Diamin.—M. von Lang.—This compound, belonging to the tetragonal system, exhibits the phenomena of circular polarisation. Its crystals have the forms p , a_1 , b_1 , &c. The ratio of the axes = 0.6692 : 1. These crystals, without exhibiting hemihedrism, polarise some to the left and others to the right. The solutions appear inactive. It is isomorphous with the sulphate of platino-diammonium, $SO_4(PtN_4H_{12})$, the crystals of which have been recently determined by Topsoe. Ratio of the axes = 0.6899 : 1. These crystals do not display circular polarisation.

Action of Sulphydrate of Potassium on the Aromatic Nitriles.—A. Weddige.—The author has caused this body in alcoholic solution to act upon pure cyanide of benzyl. The result was α -toluic amide, $C_6H_5, CH_2, CONH_2$.

Preparation of the Bromides of Quinine, Morphia, and Strychnia.—G. Macdonald.—The author prepares these bromides by exactly decomposing the sulphates by the bromide of barium, and evaporating the filtered liquid. The hydrobromate of quinine forms silky crystals, apparently anhydrous and soluble in 4 parts of cold water.

Reactions of Apomorphia.—MM. Quehl and Kœhler.—Apomorphia gives with sulphocyanide of potassium a white curdy precipitate, soluble in heat. With the yellow ferrocyanide, the solution becomes reddish and opalescent, and deposits fine flocks, which separate more quickly if heated, agglutinate, and turn green. The red (ferri-) cyanide gives a curdy precipitate, which turns violet on heating. Tannin gives a greenish yellow precipitate, which

does not dissolve on heating. With chloride of gold, there is formed a bulky purple precipitate. With picric acid, there appears, even in very dilute solutions, a lemon-yellow precipitate soluble on heating. Sulphate of copper gives a bluish turbidity, which turns green on heating. Iodide of potassium gives a blood-red precipitate, which disappears on heating. Stannous chloride produces a white precipitate, soluble on heating.

Researches on Curarin.—A. Flückiger.—With oxidising agents in presence of sulphuric acid, curarin gives the same violet colouration as strychnia, but the purity of the shade is injured by a brown accompanying body. If a saturated solution of bichromate is added to extract of curare, preferably prepared with dilute glycerin, uncrystallisable chromate of curarin is precipitated, whilst that of strychnin crystallises readily. Chromate of curarin dissolves in sulphuric acid with an intense, but transient, blue, while the chromate of strychnia becomes violet.

New Researches on the Coagulation of Fibrin.—A. Schmidt.—To precipitate completely the fibrino-plastic matter from serum, four drops of acetic acid should be added to 10 c.c. of ox-blood diluted with 15 volumes of water, and free from globules. All substances which decompose oxygenated water seem by their mere contact to promote the coagulation of fibrin.

Quick Bleaching.—The goods are plunged in a bath containing 2.5 to 3.3 kilos. of chloride of lime per hectolitre of water. After six to twelve hours, it is washed, and boiled two to four hours in a bath of carbonate of soda, containing 650 grms. of soda per hectolitre. If the fibre is very hard it is plunged, before boiling in the soda bath, into an acid bath containing 3 kilos. of sulphuric acid per 100 litres, and allowed to drain before boiling. It is then washed, and put in a bath, hot or cold, of 2.5 to 3.3 kilos. of chloride of lime, and 700 grms. of soda per hectolitre, and washed after four to six hours.

Use of Bisulphide of Carbon in Cleansing Wool.—M. Jean.—The sulphide of carbon does not injure wool in the cold, and removes the grease readily. Its removal by means of a current of cold air is tedious, and involves considerable waste. If steam or hot air be employed, the wool loses its softness and elasticity, and takes a permanent yellow tone; benzol is therefore far preferable.

Reimann's Färber Zeitung, No. 39, 1873.

This number contains a receipt for a safflower-rose on glazed calico. The dressing consists of 50 lbs. of wheat-starch, 20 lbs. of wheat-flour, 4 lbs. of white wax, and 6 lbs. of cocoa-nut oil, a little sulphuric acid being added to the water in which the starch is mixed.

There are also receipts for a light and a deep prussian blue on glazed calico; for a green (extracts of indigo and of quercitron) on jaconnets; a peach-wood crimson on glazed calico and jaconnet; a brown on calico with Bismarck brown and magenta; a grey drab on wool; and a scarlet on woollen cloth and flannel; also, a blue (soluble aniline blue) and a coffee-brown on plush; a violet on woollen yarn. The mordant in this case consists of 1½ ozs. of tannic acid dissolved in hot water in which ¼ oz. of Marseilles soap is next dissolved; ½ oz. of rape oil is next added, and stirred up till it forms an emulsion. The liquid is used at 60° R. The bleached yarn is worked in this mordant for fifteen minutes, and then withdrawn. The colour-bath, at the same temperature, is prepared with 5 ozs. of alum and the clear solution of 1 oz. of methyl violet.

There is also a prescription for a light green on cotton yarn, the colour being methyl green fixed with tannic acid.

The editor gives a receipt for a brown on shoddy, containing a mixture of cotton, called on the Continent "velour." To 100 lbs. of this material, make up a bath of 30 lbs. of fustic, 3 lbs. of alum, 2 lbs. of prepared tartar, and 1 lb. of blue vitriol, in which the shoddy is boiled for

half an hour. To the same lot are then added 1 lb. of chromate of potash and ½ lb. of "aniline red," "ruby," or "aniline crimson," known on the Continent as "rosain." The dyeing is carried on at a gentle boil, and turmeric added to modify the shade. Logwood may be used, if needful, to darken. Aniline red is a refuse magenta; it is dissolved in hydrochloric acid, and boiled in water previous to use.

Test for Chrome Yellow and Orange.—M. Duvillier.—The author proposes to test these colours for sulphate of lead by heating 1 part of the colour with 3 parts of nitric acid at 1:420, 2 parts of distilled water, and ½ part of alcohol. The chromic acid set at liberty oxidises the alcohol. The mixture is heated till nitrous fumes are no longer given off. The remaining liquid contains nitrate of lead and chromic oxide, and a white precipitate of nitrate of lead, mixed with sulphate if any be present. The whole is mixed with water, and boiled, when sulphate of lead alone remains. A much simpler process is to treat the sample with potash lye, when the colour dissolves and sulphate of lead remains. The possible presence of the sulphates of strontia and baryta has been overlooked by the author, upon whom Dr. Reimann passes some very severe strictures.

Protartar for Woollen Dyeing.—10 kilos. of alum dissolved in 40 litres of hot water; 3.5 kilos. of oxalic acid, dissolved in 20 litres of hot water, and 2 kilos. of acetic acid. As compared with tartar, this mixture is said to effect a saving of 50 per cent.

No. 40, 1873.

This number contains receipts for a catechu brown on glazed calico; an iron buff on stout cotton goods; for a deep olive-green and a drab on wool; a coal-black, a blue-black, and a deep corinth on plush; also, a black on cotton yarn, capable of bearing milling; and a blue on shoddy, the cotton in which has been first destroyed by the vapour of hydrochloric acid, and the residue neutralised with chalk. In dyeing, a preparation is used, known as "shoddy-carmide." It is made by dissolving in two pails of hot water—12 lbs. of alum, 9 lbs. of indigo-carmine, and 3 lbs. of soluble aniline blue.

Preparation of the Hair of Rabbits for the Manufacture of Felt Hats.—These hairs were formerly treated with a solution of mercury in nitric acid, for the purpose of enhancing their felting properties. A mixture of nitric acid and treacle is proposed as a substitute.

No. 41, 1873.

This number contains receipts for an iron-grey on silk; a "naturel" on stout cottons and on gauze; for greys on a variety of materials; for a black on half-worn clothes; for a medium brown, a yellow-brown, and a dark and light brown on plush; a white on wool, blued slightly with alkali-blue R, or methyl-violet BBBBB; a violet-brown colour for printing on cotton yarns (warp printing); and a flavin-yellow on calico.

Archiv der Pharmacie, July, 1873.

Sugar Found in Grass Roots; and on Triticin, a New Carbohydrate from the Roots of Triticum repens.—(Conclusion).—H. Müller.

Oleate of Mercury with Oleate of Morphia.—Ch. Rice.

Cheap Disinfectant.—E. C. C. Stanford.

Action of Dilute Saline Solutions on Lead.—M. P. Muir.

Colouration of Chloral Hydrate with Oil of Pepper-mint.—C. Jehn.

Tests for Creosote and Phenol.—J. A. Flückiger.

Detection of Alum in Bread.—J. Hornley.
Distribution of Nitrogen in Certain Kinds of Straw.
—C. Schneider.

MISCELLANEOUS.

University of London.—The following is a list of the candidates who have passed the recent Second B.Sc. examination:—First Division—J. A. Hullard, First M.B., University College; L. Lyell, private study; A. M. Marshall, B.A., St. John's College, Cambridge; H. S. Robertson, B.A., Old Trafford School and Owens; C. A. Weber, B.A., University College; J. C. Witton, private study. Second Division—J. Barnes, Owens College and private study; C. Bulbeck, private study; F. Chapple, B.A., Wesleyan College, Westminster; A. W. Fuller, Owens, and Emmanuel, Cambridge; C. W. Huson, Queen's College, Liverpool; A. S. Napier, Owens College; A. Speers, private study; J. H. Taylor, M.A. Oxon and Camb., private study; S. H. Vines, First M.B., Christ's, Cambridge, and Guy's Hospital; W. B. Worthington, Owens College.

Dr. Emerson Reynolds.—On the 24th ult., Dr. Emerson Reynolds, Professor of Analytical Chemistry to the Royal Dublin Society, and Keeper of the Mineral Department, was appointed Professor of Chemistry to the Royal College of Surgeons in Ireland. On the 14th inst., Dr. Reynolds was appointed Examiner in Medical Jurisprudence and Toxicology in the Queen's University in Ireland.

The Late Dr. Crace-Calvert.—We are informed that Mr. William Thomson will, in conjunction with Mrs. Crace-Calvert, continue to carry on the business of Analytical Chemist, formerly conducted by Dr. Crace-Calvert, at the Royal Institution, Manchester, under the firm of Crace-Calvert and Thomson. Mr. Thomson has had more or less the management of the business for the last five years.

NOTES AND QUERIES.

Tartaric Acid.—Would you kindly oblige me by informing me through your valuable paper how the tartaric acid might be recovered from a solution of tartrate of soda?—C. SMITH.

Indigo.—Will some one of your readers inform me where I can find an account of the most recent and fullest researches upon indigo. Also the best description of apparatus and processes used in the manufacture of what is known commercially as extract of indigo.—COLOUR.

The Estimation of Sulphur in Pig-Irons.—The "simple and ready method" described in p. 248 CHEMICAL NEWS, by Mr. Piessé, is a very old one in common use in metallurgical laboratories, and described in rudimentary metallurgical treatises. The result obtained is somewhat below the truth, as some of the sulphur may escape oxidation, and pass off in combustion with the hydrogen evolved. I have found that nitric acid, sp. gr. 1.2, is more convenient as a solvent than aqua regia; though liable to the same objection the loss of sulphur is less variable than when aqua regia is used.—W. MATTIEU WILLIAMS.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the purification of water and apparatus connected therewith, together with the mode of cleansing the same. Arthur Charles Henderson, of the firm of Henderson and Co., British and Foreign patent agents, 31, Charing Cross, Middlesex. (A communication from Gustave Demailly, civil engineer, Brussels.) February 18, 1873.—No. 597. This invention consists in purifying water before use, either in domestic or industrial purposes, by a combined chemical and mechanical process, freeing it from calcareous and other matters held in solution, by adding thereto a small proportionate quantity of solution of caustic lime, which, troubling the water, presents a precipitate formed by the action of the carbonic acid by immediately depositing carbonate of lime, so that, instead of having to treat matters in solution, it merely remains to operate on matters in suspension. The apparatus for effecting this consists of a filter formed of a cylindrical

vertical case of sheet- or cast-iron furnished with a lid; in this another cylinder is contained, which is the filter proper, also formed of sheets of cast- or sheet-iron, one at the top and the other at the bottom, and united by three concentric cylinders of perforated sheet-iron. These cylinders form two annular capacities supplied with filtering matter composed of felt or wool rendered imputrescible. The water arrives in the filter by a tap, spreads itself between the envelope and the filtering cylinder, then by pressure it traverses the latter, and makes its exit by a discharge-tap perfectly clear and freed from all matters in suspension. The cleansing of the filter is effected, without the necessity of taking the apparatus to pieces, in the following manner:—When the steam-engine is stopped, the tap admitting water into the filter is closed, as well as the exit-pipe communicating with the feed-pump, which allows of free communication, with the central pipe of the filter and water-draught of the generator. On opening the discharge-tap, it will at once be seen what has taken place. The pressure of the generator sends the water already purified into the central pipe of the filter; this water traverses inversely the beds or layers of filtering matter, and draws along with it the foreign organic matter arrested during filtration, and flows out by the discharge-tap. The whole cylindrical body is also movable on a pivot, and is made to revolve so that it comes under the influence of a brush fixed vertically at the inner side of the case, which suffices to dislodge any residue.

Improved combinations of ingredients for removing acidity from ales, beers, porters, wines, &c., and also to preserve them from acidity. Charles William Sutton, of the firm of Sutton & Company, of Stowmarket, Suffolk. February 18, 1873.—No. 599. This consists in the employment of hydrate of lime and chloride of sodium in combination, or hydrate of lime and chloride of ammonium, in suitable quantities with distilled water for depriving ales, beers, wines, &c., of excess of acid, and also for preserving them from acidity.

Improvements in photo-mechanical printing, and in apparatus to be used in such printing. William de Wiveleslie Abney, St. Margaret's Street, Rochester, Kent. February 19, 1873.—No. 615. This invention consists in coating a flexible sheet of paper or linen with a solution of gelatine made sensitive to light with bichromate of potash, with or without the addition of chrome alum or other analogous substance. The sheet so coated is dried and exposed to light under a photographic negative, and after having been washed is placed upon a flat support, upon which it is pressed, and the picture upon its surface is inked with greasy ink by means of soft rollers, and is then transferred to the surface of stone or zinc in the usual way, and pictures are obtained from it in a lithographic printing press. By this method the film is inked whilst still wet, and the photographic negative need not be reversed, nor is it necessary that it should be of great density in its opaque parts.

Improvements in the manufacture of mortar, beton, and concrete. Humphrey Chamberlain, engineer, Round Green, Barnsley, York. February 19, 1873.—No. 623. This invention consists essentially in the application and use to, and in the manufacture of, mortars, betons, and concrete of the waste lime from gas purifiers, which has hitherto been treated as a comparatively useless refuse. I have found by experiment that "gas lime," by which name such before-mentioned waste lime is known, produces an equally good or superior mortar to fresh lime. It is simply requisite to grind it up in the usual mortar-mill, or to mix it as ordinary lime with sand, ashes, and such like materials. The said refuse lime is also suitable as a substitute for fresh lime in making concrete or "beton," which may or may not, as required, be moulded into bricks or blocks in any well-known manner, and in the event of a very hard substance being required, a portion of Portland cement may be used in combination with the said refuse lime.

Improvements in purifying dusty and otherwise impure casks, and in seasoning new casks and timber to be made into casks. R. J. Tremlin, brewer, Maidstone, Kent. February 20, 1873.—No. 626. This Provisional Specification describes employing bisulphite of lime mixed with water, heated by steam, or it might be hot air being blown into or through it, or being otherwise heated.

Improvements in the mode of and apparatus for treating marine plants called sea-weed, sea wrack, and algae, in order to obtain useful products therefrom for industrial and other purposes. Michael Henry, patent agent, Fleet Chambers, 68, Fleet Street, London. (A communication from the Société Collet et de Lavillasse, Landerau, and 17, Boulevard St. Martin, Paris.) February 20, 1873.—No. 652. Sea-weed, wrack, algae, or marine plants are treated preferably when fresh from the water, before drying. They are incinerated in a close furnace into which air is blown or forced. The gases or vapours, with the matters held in suspension, are condensed in damp condition. The utilisable products that escape from the main combustion may be brought back to the furnace. A furnace is described in which hollow fire-bars (wherein air or water circulates) are used, and the materials fall on to a plate, under which there may be a second grate, and thence they are raked into moulds. The gases and vapours, with the matters which they hold in suspension, pass into a chamber in which there is an air or water circulation. Cold water may be showered in. The products are collected in channels leading to a receiver. A fan or blower extracts the air from the chamber and passes it into the furnace.

Improvements in arrangements and apparatus for preparing peat, small coals, coal-tar, petroleum, or other similar substances, for fuel. Murdoch Campbell, Clonreher Castle, Maryborough, Queen's County, Ireland. February 21, 1873.—No. 656. Improvements consist in macerating the peat into pulp, by means of suitable mills, without water, or with water, petroleum, or coal-tar added thereto; afterwards it is moulded into solid, hollow, or perforated blocks or bricks, by passing it through the dies of brick-making machinery. Small coals and coal-tar are also mixed together and moulded into blocks or bricks in like manner. The drying shed is heated artificially and ventilated by a self-acting screw cowl fitted on top of shed.

THE CHEMICAL NEWS.

VOL. XXVIII. No. 731.

ALUM IN BREAD.

It is unfortunate that proceedings under the Adulteration Act should have been taken in the matter of the so-called adulteration of flour and bread with alum. In the first place, it is highly probable that this so-called Adulteration is a meritorious Act, and that the inventor of it deserves a civic crown, as would be due to him who should increase the harvest every year. Alum is added to flour and bread in order that flour, which otherwise would not make good bread, may be enabled to do so. By treatment with a trace of alum, flour of doubtful soundness is endowed with soundness. For this purpose a proportion of alum is required which does not exceed 20 grains to a 4-lb. loaf.

One of the most important functions of the public analyst is to withstand popular clamour and to oppose professional prejudice—prejudice which owes its origin to imperfect acquaintance with the matter in hand. And this case is an illustration in point. The 20 grains of alum have been sensationally dealt with; and the people, and professional persons who ought to know better, have attributed tanning of the stomach and ruin of the digestion to these 20 grains of alum in the 4 lb. loaf.

Nothing is easier than to show the unreasonableness of such notions; and perhaps some of those persons who are suffering from them will be surprised to be told that the phosphate of potash in a 4-lb. loaf (and which existed in the flour of which the 4-lb. loaf is made) is far more than enough to transform the alumina contained in the 20 grains of alum into phosphate of alumina.

It is useful to call to mind that of the 20 grains of alum about half is water, and that there are only about 2½ grains of real alumina (Al_2O_3) in 20 grains of alum.

Under these circumstances, we are almost tempted to rejoice in the difficulties which beset the public analyst in his attempts to detect traces of alum in bread. We are not surprised that the public analyst returns bread which has been purposely alumed as being devoid of alum, inasmuch as the detection of traces of alum in presence of the constituents of the ash of bread is one of the most difficult problems of chemical analysis.

In connection with this subject the following remarks on the detection of alum in bread, published by the Editor of this journal some years ago, may not be inappropriate at the present time:—

"This problem is one of far more difficulty than is generally imagined, and it is doubtless to this fact that the discordant results obtained by different analysts are to be attributed: one stating that out of sixty-four samples of bread purchased at various shops in poor neighbourhoods at the East of London, where, if anywhere, adulteration would be practised in the most barefaced manner, not a single one was found to contain alum; whilst another analyst, with equal positiveness, mentions the name of a baker who is, in his opinion, almost the only person in a large district at the West End of London who sells unadulterated bread, and proceeds to state that more than

87 per cent of the bread in London is adulterated. Very few of those who have published anything on this subject give details respecting the process they adopt, but in most instances it seems to be somewhat to the following effect:—The bread is first charred and burnt nearly to an ash; the latter is then boiled in diluted hydrochloric acid, with which a little nitric acid has been mixed; ammonia is then added, and the precipitate which it produces is boiled in potassa. After filtration, hydrochloric acid is to be added in excess, and then ammonia, when it is supposed that the precipitate will consist of alumina. With a pure solution of alumina to start with, doubtless this process would give accurate results; but it must be remembered that in bread the alumina would be accompanied by phosphoric acid, as well as phosphate of lime and phosphate of magnesia, each of which would make its appearance in the last precipitate with ammonia, and would consequently pass for alumina. But, granting that this tendency of the phosphates of lime and magnesia to simulate the reactions of alumina had been provided against, it seems to have been almost entirely overlooked by popular writers on this subject that whenever alumina and phosphoric acid meet together in solution, they adhere with the greatest pertinacity, and will infallibly appear together in the last precipitation. I should not have deemed these points worthy of mention did I not know that many analysts are habitually employing similar processes to the above, and are even estimating quantitatively the amount of adulteration in bread by weighing this precipitate of the mixed phosphates of lime, magnesia, and alumina, and calculating it as pure alumina.

"My attention was first drawn to this subject by the fact that a sample of bread which was known to be entirely free from adulteration had been pronounced by a somewhat experienced analyst as being largely adulterated with alum. My assistance was asked in order to disprove this injurious allegation, and, having accordingly submitted the subject to a somewhat lengthened examination, I am induced to lay the results before the readers of the CHEMICAL NEWS, in the hope that, when the attention of chemists is drawn to the subject, it may be investigated as fully as its commercial importance deserves.

"The great difficulty in my hands has been to devise a process which should not confound other things with alumina. It was easy to frame various modes of operating by which a minute trace of alumina could be detected, but I was for a long time baffled by finding that they were equally delicate in their reactions, whether alumina were present or not. In fact, I do not hesitate to say that the accurate analysis of a mixture of those phosphates which are precipitated from an acid solution by ammonia is one of the most difficult problems in inorganic chemistry that the chemist is liable to meet with in technical analysis. I do not pretend to have yet solved the difficulty, but the process which I have at last adopted has at least the merit of not showing the presence of alumina when that body is absent. It has, on the other hand, the inconvenience of being rather tedious in its manipulation, and to some may seem to be needlessly complicated. No one can be sensible of this fact more than myself; but of the numerous methods which I have tried, both with and without separating the phosphoric acid, this was the only one which invariably gave me trustworthy results.

"The bread, of which at least 500 grains should be taken, is first to be incinerated in a platinum or porcelain dish, until all volatile organic matter has been expelled and a black carbonaceous ash remains. The temperature must not be raised much beyond the point necessary to effect this. Powder the coal thus obtained and add about thirty drops of oil of vitriol, and heat until vapours begin to rise; when sufficiently cool, add water and boil for ten minutes. Filter and evaporate the filtrate until the fumes of sulphuric acid begin to be evolved, when ten grains of metallic tin and an excess of nitric acid must be added, together with water, drop by drop, until action between the acid and metal commences. When all the tin is

oxidised, add water and filter. Evaporate the filtrate until fumes of sulphuric acid are again visible, when more water must be added, and the liquid again filtered if necessary. To the clear solution now add tartaric acid, then ammonia in excess and sulphide of ammonium. Evaporate the liquid, containing the precipitate suspended in it, in a dish, until all the smell of sulphide of ammonium has disappeared. Filter, evaporate to dryness, and ignite to get rid of the organic matter. Powder the black ash, boil it in moderately strong hydrochloric acid, filter, add a crystal of chlorate of potash, and boil for a minute. Now add chloride of ammonium and ammonia, and boil for five minutes. If, at the end of that time, any precipitate is observed it will be alumina. From the filtered solution, if oxalate of ammonia be added, the lime will be precipitated; and if to the filtrate from this, ammonia and phosphate of soda be added, the magnesia will come down."

PRELIMINARY INVESTIGATION OF THE FLUORESCENT AND ABSORPTIVE SPECTRA OF THE URANIUM SALTS.*

By HENRY MORTON, Ph.D.,
and H. CARRINGTON BOLTON Ph.D.

(Continued from p. 259).

Double Sulphates.

Uranic sulphate has heretofore been known to form the following double salts:—

The last-named was obtained by Berzelius, but Ebelmen and Péligot could not reproduce it. To this list we have added the following new compounds:—

The history of the ammonio-diuranic sulphate has been already given in a previous part of this paper, and we need only add here that we have as yet been unable to prepare it otherwise than by the decomposition of the

When solutions of equivalent weights of uranic sulphate and rubidium sulphate are brought together, and the proper degree of concentration has been reached, warty concretions of minute crystals form, possessing a hue of remarkable beauty and a brilliant fluorescence. So strong is this that the white porcelain dish in which the crystals form appears pink by contrast.

Thallio-uranic sulphate forms in a precisely similar manner, but is of a golden yellow colour with a fine lustre, but very slight fluorescence. It is not readily soluble in water, but is very stable, being easily re-crystallised from hot solution. Analysis of these salts has not been completed in time for insertion in this preliminary notice.

We will now pass to the optical study of these salts in their alphabetical order.

Ammonio-Uranic Sulphate, $\text{U}_2\text{O}_3\text{SO}_3 + \text{NH}_4\text{OSO}_3 + 2\text{H}_2\text{O}$.—The spectrum of this salt has been already described, but for completeness we will here reproduce it with some additional data. The bands of this substance are distinguished by great abruptness on their more refrangible side, rising as it were suddenly to a narrow brilliant line, and then fading off gradually on the lower side in a manner suggesting a rounded convex surface. Their positions are shown in 1 of Fig. 20.

In the first experiments made with this salt it was heated to about 200°C . to drive off its water, but subsequent experience showed that the same result might be reached by a continued application of a temperature of 100°C . Two atoms of water in this salt would amount to 6.71 per cent; and it was found that a specimen bottle placed in a hot-water oven continued to lose weight for about twelve hours. At the end of this time its total loss was 7 per cent, and its weight then remained constant, even when it was heated to about 250°C . Its fluorescent spectrum was then that shown at 3 of Fig. 20. Its characteristic was a new position of the bands, and a much more rounded and less brilliant appearance. This salt does not appear to form any mono-hydrate, and in fact presents a great contrast to the uranic sulphate and sodio-uranic sulphate as regards the fixity of its two forms, the normal or bihydrate and anhydrous state. The position of its absorption-bands has been already shown at 10 of Fig. 1, and will also be seen at 1 of Fig. 19.

Ammonio-Diuranic Sulphate, $2(\text{U}_2\text{O}_3\text{SO}_3) + \text{NH}_4\text{OSO}_3$.—This salt, which, as we have before stated, is obtained by heating the dried ammonio-uranic sulphate in an open vessel to a temperature of about 325°C ., or, in other words, a heat competent to fuse lead in the same vessel, and which will then bear a temperature little short of redness

- 5 Sodio-uranic sulphate.
- 6 Thallio-uranic sulphate.

ammonio-sulphate as there described. Both the magnesium salts were formed under conditions seemingly identical, when a cold solution of the mixed sulphates was allowed to concentrate over sulphuric acid.

* Communicated by President Morton.

without further decomposition, yields a spectrum such as is represented in 5 of Fig. 20, and whose bands are as bright and sharply defined on the upper edge as those of the hydrated ammonio-sulphate; from which they are to be distinguished only by their position, and perhaps by their greater breadth descending more gradually into the

dark spaces on the lower side. The bands near 70 and 80 of the cut are not correctly shown, the first being too low, and the second too high. They should show an even spacing, one having its upper edge at 70.5 and the other at 80. The absorption spectrum of this salt is shown at 2 of Fig. 19.

Magnesian-Uranic Sulphate.—As we have already noticed, a mixture of uranic and magnesian sulphates will form two compounds, one of these, which seems easy to reproduce, having the formula $U_2O_3SO_3 + MgOSO_3 + 4HO$. The other

relation; A being the normal salt, and B that which we can only name by a conjecture:—

Fluorescent Spectra of Magnesio-Uranic Sulphates.

Bands.	1.	2.	3.	4.	5.	6.	7.	8.
A ..	—	40.4	48.0	55.5	65.7	74.6	84.8	91.6
B ..	—	44.8	53.0	66.4	70.8	81.0	90.5	96.0

The measures here given are of the upper edges of bands except the 8th, which is measured at its centre. The absorption spectrum of the normal salt, A, is given at 3 of Fig. 22, and is characterised by the absence of the lower bands found in other double sulphates.

Potassio-Uranic Sulphate, $U_2O_3SO_3 + KO_2SO_3 + 2HO$.—This salt readily crystallises out when a solution of the mixed sulphates in atomic proportions is allowed to evaporate in the air; it forms warty concretions of minute crystals of a yellow-green colour and very bright fluorescence. In this state it contains 2 atoms of water, and shows the spectrum represented in 1 of Fig. 24, which is of the normal character, with a sharp termination of each band on its upper edge, and the bands peculiarly broad and bright.

This salt suffers no change by heating or drying at 100° C., but if dried at 150° C. it loses all its water, and its spectrum changes to that shown at 2 of Fig. 21, in which the bands are much rounded, and displaced a little upward in the spectrum. It would thus appear that this salt can exist, and display fluorescent action as a bihydrate and anhydrate, but we have obtained no evidence of its forming a monohydrate.

The absorption spectrum of the hydrated salt will be seen at 1 of Fig. 19, being indistinguishable from that of the ammonio-salt. The spectrum of the anhydrate is more difficult to observe, but by using the substance in powder with a little oil between slips of glass we can make out bands whose centres are at 93.7, 101.0, 111.7, and 124.4 respectively, and which are therefore quite unlike those of the normal salt.

Rubidio-Uranic Sulphate, $U_2O_3SO_3 + RbOSO_3 + 2HO$.—The preparation of this salt we have already described, and we will therefore pass at once to its fluorescent spectrum. In this the bands are much blended or rounded, and are decidedly lower than the corresponding ones of the potassium salt. Their brightest parts are located as follows:—

Fluorescent Spectra of Rubidio-Uranic Sulphate.

1.	2.	3.	4.	5.	6.	7.	8.
34.0	41.6	49.2	57.6	66.7	76.0	85.2	94.8

This substance loses 2 atoms of water if it is dried at 100° C., but its fluorescent spectrum is not changed as regards the position of its bands; the brightness of its fluorescence is, however, reduced. An exposure to a yet higher temperature (180° C.) causes a slight loss of weight (0.6 of 1 per cent), and yet further reduces its fluorescence without other effect. The absorption spectrum of the normal salt will be found at 4 of Fig. 19.

Sodio-Uranic Sulphate, $U_2O_3SO_3 + NaOSO_3 + 5HO$.—This salt presented more difficulties at the outset than any other, and, as might be expected, has yielded some very curious results. Thus a certain specimen was observed to yield the peculiar spectrum shown at 2 of Fig. 22, while the rest of the crop of crystals in another bottle from which it had been taken showed nothing of the sort. A prolonged study of this body has evolved the following facts, and has shown that many more await further investigation:—This salt in its normal state, containing 5 atoms of combined

FIG. 20.

FIG. 21.

Potassio-Uranic Sulphate.

FIG. 22.

Sodio-Uranic Sulphates.

we have only succeeded in obtaining once in small quantity. This and the fact that it was then mixed with magnesium sulphate, render an accurate analysis impossible, but a determination of the water and sulphuric acid seems to indicate that the body has the formula $U_2O_3SO_3 + MgOSO_3 + 7HO$. We would, however, only present this as a suggestion. The two salts yield fluorescent spectra, which are entirely distinct in the positions of their bands, although both are alike, and of what we have called the normal form in their general character. The following table will show this

water yields the spectrum shown at 1 of Fig. 19, which is of the normal type. A portion of this water is, however, lost with great ease, occasioning the formation, under ordinary conditions, of mixtures of several hydrates. Some of these we have been unable to isolate and determine, but we have found that, by gradually drying at a temperature of 150°C ., we obtain a monohydrate whose spectrum is that shown at 3 of Fig. 19. If the salt in a damp state is placed suddenly in the oven at 150°C ., it will lose almost all its water, and give a spectrum sensibly continuous; in this condition it may be dried at 200°C . without suffering any change. When heated to 250° to 290° the salt loses all its water, and then acquires a spectrum such as is shown at 4 of Fig. 19, in which each band looks like a prismatic column. Under various conditions, which we have not yet been able to determine with certainty, intermediate amounts of water are lost, and mixtures of other hydrates are produced, in which, no doubt, salts with 2, 3, or 4 atoms of water are involved. These, once formed, will, like the corresponding hydrates of uranic sulphate, maintain themselves in the presence of desiccating treatment, which would deprive the normal salt of much more water. The absorption spectrum of the normal salt is shown at 5 of Fig. 19. It is, perhaps, unnecessary to state that the peculiar spectrum shown at 2 of Fig. 22 is believed to be produced by three or more overlapping spectra belonging to as many mingled hydrates.

Thallio-Uranic Sulphate, $\text{U}_2\text{O}_3\text{SO}_3 + \text{TiO}_2\text{SO}_3 + 3\text{H}_2\text{O}$.—This substance has a very faint fluorescence. Bands can be made out at $92.4(?)$, 35.6 , and 76.0 ; below the first of these three seems to be a faint continuous spectrum. This salt loses $3\text{H}_2\text{O}$ and all its fluorescence by drying at 100°C . Its absorption spectrum is shown at 6 of Fig. 19.

NOTES OF WORK
BY STUDENTS OF PRACTICAL CHEMISTRY
IN THE LABORATORY OF THE
UNIVERSITY OF VIRGINIA.

(No. II.)

Communicated by J. W. MALLETT,
Professor of General and Applied Chemistry in the University.

- (1). *On the Best Mode of Converting Calcium Oxalate into Carbonate in the course of Analytical Work.* By Mr. J. R. McD. IRBY, of New Orleans, Louisiana.

CALCIUM precipitated as oxalate is sometimes weighed as such after drying at 100°C ., is sometimes converted into carbonate by heating to a carefully regulated temperature just short of redness, sometimes converted into lime by heating to bright redness or beyond, and sometimes given the form of sulphate by treatment with sulphuric acid or ammonium sulphate.

Of these four modes of procedure, although accurate results can be obtained by any one of them,* the second is, on several grounds, to be preferred for general use.

If the oxalate itself be weighed, an unburnt filter, previously tared when dried at 100°C ., has to be weighed with it, and the errors which may be allowed to arise from hygroscopic moisture affecting this filter at either of its weighings, and the tube or watch-glasses used to contain it are more likely to influence the result to a serious extent than those from similar causes when but the ash of a filter and a small crucible are concerned.

The conversion into caustic lime requires a very strong heat, generally obtained by means of a blast lamp, the blowing being kept up for some time. The last traces of carbon dioxide are driven off with difficulty, and the platinum crucible is liable to alter slightly in weight, while the risk of mechanical loss from the blast, and the great readiness with which moisture is taken up from the

atmosphere by the lime during cooling and weighing, are not to be altogether overlooked.

The acid fumes given off during the conversion into sulphate and final evaporation are annoying, and the heating is tedious and requires very careful watching to prevent loss.

Pure calcium carbonate is undoubtedly the most stable and desirable form in which to obtain the final product for weighing, and if at once obtained by carefully managed heating of the oxalate, as may be accomplished in well-trained hands,* leaves nothing to be desired; but if the temperature be allowed to rise a little too high, and a little caustic lime be formed, the necessary evaporation with solution of ammonium carbonate is tedious and troublesome, and cannot be hastened without almost certain loss from spitting. Moreover, while a very small quantity of lime can thus easily be restored to the condition of carbonate, if any considerable amount of material have to be dealt with the moistening and evaporation will often need to be repeated more than once before the weight becomes constant. The object in heating is, therefore, to so regulate the temperature as to ensure the complete destruction of all oxalate, and to avoid altogether the decomposition of the carbonate. The statement of the writers on analytical chemistry, that the proper temperature is represented by very low redness, or should be just short of redness, is wanting in precision. Working at night or in the daytime, by bright sunlight or on a dark, cloudy afternoon, one's estimates of barely visible redness will represent by no means a small range of temperature, and it needs a good deal of personal supervision to teach a new laboratory student exactly how to proceed, so as to obtain at once, without the delays above referred to, a result so often called for as an accurate determination of calcium.

In order to simplify and give greater precision to the details of the process, it was suggested to Mr. Irby to get some better measure of the temperature really required, and to find, if possible, some empirical rule for its ready production and regulation.

Not having at command one of Siemens's electric resistance pyrometers, it was attempted to estimate the temperature needed for the decomposition of the oxalate by comparison with the melting-points of some of the metals.

Calcium oxalate (specially prepared and found to be quite pure, and fully dried at 100°C .) heated to the melting-point of lead for a short time, was found, on cooling, to have begun to decompose, but the extent of the change was quite small. At just the melting-point of zinc the weight could easily be reduced to within one or two per cent of the theoretical amount, but several hours' exposure to this temperature scarcely produced complete reduction to carbonate. Several metallic alloys were tried, in order to get from some one of them a barely-fused bath of the proper temperature, but they all gave too much trouble from surface oxidation and the tendency to separate into a more and a less fusible portion. Finally, it being ascertained that a heat but very little beyond the melting-point of pure zinc was required, the following arrangement was found practically successful.

A solid cylinder of cast-iron, smoothly turned, 53 m.m. high and 66 m.m. in diameter, had a cylindrical hole of 40 m.m. deep and 40 m.m. diam., drilled into the upper end, thus producing a sort of crucible with walls and bottom 13 m.m. thick. A turned disc of cast-iron, 58 m.m. in diameter and 6.5 m.m. thick, with a little knob in the middle of the upper surface to serve as a handle, formed a cover; and in the upper surface of this cover, two hemispherical cavities, each 10 m.m. in diameter, were drilled at opposite sides, the centre of each 15 m.m. distant from the edge. Round the outside of the cylinder a little groove was turned, which enabled the whole to be supported over a lamp by a stout iron wire triangle.

* See paper by Aug. Souchay in Fresenius's *Zeitschr. f. Anal. Chem.* 10 Jahrg., 3 heft., s. 323, and remarks upon same by Fresenius in same periodical, s. 326.

* Fresenius, in his excellent "Anleitung zur Quant. Chem. Anal." 5 Aufl., s. 201, has given minute directions as to the details.

The figure shows this thick walled crucible and cover in vertical section. The total weight was about 1050 grms.

In the little cavities (*a a*) bits of metallic zinc of about a gramme each were placed, a piece of porcelain, such as a small crucible cover, was placed in the bottom of the cast-iron vessel, and upon this a platinum or porcelain crucible (the latter being found to answer best, on account of its inferior conducting power) containing the calcium oxalate to be heated. Gas from a Bunsen burner with tube of 9 m.m. diameter was used as the source of heat, and the position of the burner was so regulated that, when the stopcock was fully opened, the flame played

over the bottom of the cast-iron block and about one-fourth up the outside all round. With quantities of 1 to 1.5 grm. of oxalate, the full flame of the lamp was turned on at once, the mass of iron in the block ensuring sufficiently gradual heating, and it was then only necessary to notice when the bits of zinc in the cavities of the iron cover had fully melted; the decomposition was then complete. This took about thirty minutes, but during that time no attention on the part of the operator was needed. The calcium carbonate left in the crucible was quite free from caustic lime. The following are two examples of the results:—

Calcium oxalate taken.	Calcium carbonate obtained.	Calcium carbonate calculated.	Lime (derived from oxalate) as calculated from carbonate.	Lime calcu- lated directly from oxalate.
Grm.	Grm.	Grm.	Per cent.	
1.0388	0.7109	0.7115	38.32	38.36
1.5765	1.0792	1.0798	38.33	"

It proved to be important that the decomposition of the greater portion of the oxalate should take place without the carbon monoxide gas given off taking fire, since the additional heat produced by its combustion through and on the mass sufficed to burn a little of the carbonate into lime, and the tendency to separation of carbon (rendering the mass dark in colour) was much greater when the gas took fire, while carbon once separated could not be well burnt off again without increasing the heat too much. The effect of too rapid heating, attended with the burning off of carbon monoxide, is shown by the following results, obtained in experiments in which the maximum temperature derived from the lamp was no higher than in others of entirely satisfactory character:—

Percentage of Lime obtained from Oxalate.		
Found.		Calculated.
38.18	}	38.36
38.19		

Hence, when the oxalate amounted to about 2 grms., it was found better to turn on the gas to the lamp somewhat

gradually and to keep up the heat longer, about three quarters of an hour being required, while, for quantities of 3 grms., an hour was necessary.

In the course of actual analysis, the oxalate being upon a filter, as much as possible of the substance should be detached from the paper and treated as above described, while the filter itself is burnt upon the lid of the platinum or porcelain crucible, the minute residue left treated with one or two drops only of strong solution of ammonium carbonate, which small quantity can be dried up quite quickly and easily on a water-bath or gently heated sand-bath, and the cover then introduced into the cast-iron cylinder along with the crucible; the two to be taken out, cooled, and weighed together.

(2). *Analysis of Atacamite from Australia.* By Mr. J. A. CABELL, of Richmond, Virginia.

In Dana's "Mineralogy," 5th edition, p. 121, the formula assigned to atacamite is—

(old atomic weights of copper and oxygen), or 3 molecules of cupric oxide, 1 of cupric chloride, and 4 of water, the author remarking that one or two analyses give one-half more water. Rammelsberg ("Handb. d. Mineralchem.," s. 191) makes three varieties of the mineral, each containing 3 molecules of cupric oxide and 1 of the chloride, but therewith 3, 4½, and 6 molecules of water respectively.

In view of this discrepancy of results as to the amount of water, and there seeming to be no recorded analysis of Australian atacamite, a portion of a very fine, well-crystallised specimen, of rich dark green colour, from South Australia, was placed in the hands of Mr. Cabell for analysis. Sp. gr. of mineral = 4.314. The following were the results, neglecting traces of insoluble siliceous residue, ferric oxide, and alumina:—

	Found.	Calculated.
Cupric oxide	56.64	55.85
Copper	14.67	14.87
Chlorine	16.44	16.63
Water	12.02	12.65
	99.77	100.00

The figures in the last column are calculated from the formula—

which probably represents the composition of normal atacamite, while the larger proportions of water found in some of the recorded analyses may perhaps be due to alteration.

The water was determined directly by Mr. Cabell, and the facts carefully established that it had all been driven off and that no chlorine had been volatilised.

I myself obtained some years ago, from a specimen of clean, sandy atacamite from Chili (Rammelsberg, "Handw. d. Ch. Th. d. Mineral.," 5 suppl., s. 57).

Cupric oxide	55.94
Copper	14.54
Chlorine	16.33
Water	12.96
Quartz	0.08
	99.85

numbers agreeing well with the above results.

(3). *Analysis of Burnonite.* By Mr. C. E. WAIT, of Little Rock, Arkansas.

Choice fragments of beautifully crystallised burnonite, from Herodsfoot Mine, near Liskeard, in Cornwall, of sp. gr. 5.826, gave, on analysis—

Sulphur	19'359
Arsenic.. .. .	0'469
Antimony	23'577
Lead	41'949
Copper.. .. .	13'268
Iron	0'679

99'301

leading to the recognised formula for the species—

the only noteworthy point being the replacement of a little of the antimony by arsenic. This does not seem to have been before observed for bournonite, although so common in other minerals containing the sulphides of these metals. The perfectly crystallised condition of the specimen examined negatives the idea of an admixture with tetrahedrite.

- (4). *Analysis of an Iron Slag of Fine Blue Colour from Barrow Iron Works, Lancashire (England).* By Mr. J. R. McD. IRBY.

This slag was very compact, tenacious, and hard—declared by a lapidary to be fully equal in hardness to the most refractory jasper; fracture splintery and imperfectly conchoidal. Its colour was a remarkably fine blue, quite comparable with the darker varieties of *lapis lazuli*, so that a specimen cut *en cabochon* made a handsome stone for a finger ring. Sp. gr.=2'883. When reduced to an impalpable powder, it was completely decomposed by strong hydrochloric acid, with loss of colour, evolution of hydrogen sulphide, and separation of flocculent silica. It was ascertained that none of the sulphur present existed in oxidised form. Analysis gave—

		Quotients on dividing by Molecular Weights.
Silica	46'683	0'778
Alumina	5'769	0'056
Ferrous oxide	1'208	0'008
Manganous oxide.. .. .	1'062	0'007
Lime	39'168	0'699
Magnesia	0'987	0'025
Sodium oxide	1'276	0'021
Potassium oxide	0'967	0'010
Sulphur	2'074	0'065

99'194

The ratio of the oxygen in the bases to that in the silica is about 6 : 10, the slag approximating to a simple metasilicate of calcium. While the general composition is quite different from that of *lapis lazuli*, the resemblance in colour and reaction with hydrochloric acid strongly suggest the probable presence of the same or an analogous compound of sulphur with the one to which the fine blue tint of that mineral is generally ascribed. There is enough of the alkaline metals present to allow of the existence of their sulphides, according to the older view of the constitution of *lapis lazuli* and ultramarine, and more than enough aluminium for its sulphide assumed by Stein to be the cause of the colour.

- (5). *Analysis of a Siliceous Crust on the Surface of Decomposing Obsidian from the East Side of St. Castagna, Lipari.* By Mr. J. A. CABELL.

A light grey obsidian, exposed to the action of heated sulphur dioxide, air, and vapour of water, had been decomposed to the depth of 10 to 12 m.m., producing a white, opaque, porous mass, on the outside of which a delicate, warty, and vesicular crust of 5 to 10 m.m. appeared, resembling hyalite, quite colourless, most of it transparent, some portions slightly milky.

This outside transparent crust was the subject of examination. Sp. gr. (in powder)=2'062. Dissolved to the extent of one-third its weight by boiling for three

minutes with solution of caustic soda (20 per cent sodium hydrate).

After drying at ordinary temperature over sulphuric acid, from which no material loss of weight resulted, analysis afforded—

Silica	93'46
Alumina	0'37
Lime	0'74
Ferric oxide	0'37
Ferric chloride	0'15
Water lost at temp. above 100° C.	4'55
Water lost at 100° C.	0'08

99'72

The mineral is, therefore, opal silica—florite or siliceous sintra. The trace of chloride of iron comes in quite naturally from its volcanic origin. The amount of water retained after drying at 100° C. agrees very closely with the results of Gottlieb's experiments (*Journ. Prakt. Chem.* [2], vol. vi., 185-196) upon hydrated silicic acid artificially prepared by decomposition of silicon fluoride.

- (6). *Analysis of "Novaculite," or "Ouachita Whetstone," from Hot Springs, Arkansas.* By Mr. C. E. WAIT.

A very pure, snowy white specimen of this beautiful material, which has been fairly described by Dr. D. D. Owen in his "Second Geological Report on the State of Arkansas, as "equal in whiteness, closeness of texture, and subdued waxy lustre, to the most compact forms and white varieties of Carrara marble," of sp. gr. 2'649, proved to consist of—

Silica	99'635 (by diff.)
Alumina	0'113
Magnesia	0'087
Sodium oxide	0'165
Potassium oxide	trace
Iron	trace

100'000

The silica, or at any rate nearly all of it, appears to be in the crypto-crystalline, not in the amorphous or opaline form, as on boiling for three minutes with a 20 per cent solution of sodium hydrate but 1'63 per cent of the mineral was dissolved, and thirty minutes' boiling only led to 3'56 per cent being taken up.

- (7). *Analysis of Electric Calamine from Wythe County, Virginia.* By Mr. J. R. McD. IRBY.

This mineral was from the land of the late Mr. David Graham, on New River, about 10 miles above the point where it is crossed by the Atlantic, Mississippi, and Ohio Railway. It occurred in irregular masses, for the most part made up of contorted sheets 6 or 8 m.m. thick, botryoidal, and slightly stained by ferric oxide on the outer surface; pure white and nearly opaque, with radiated structure within; hardness, a little over 5; sp. gr., 3'338 at 21° C. It slowly and imperfectly gave up its water at 100° C.

In powder, and moistened with water, it dissolved easily in dilute hydrochloric acid in the cold, the solution gelatinising on standing. With strong acid, it formed a jelly at once. Acetic acid also dissolved it in the cold.

Analysis gave, for the pure mineral previously dried over sulphuric acid at ordinary temperature—

		Calculated for $\text{Zn}_2\text{SiO}_4 + \text{H}_2\text{O}$.
Silica	23'949	25'00
Zinc oxide	67'883	67'50
Water	8'133	7'50

99'965

100'00

Hence a calamine unusually free from traces of foreign substances, but with a very slight excess of zinc oxide and water.

ON THE ENERGIES OF THE IMPONDERABLES,
WITH ESPECIAL REFERENCE TO THE
MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 238).

TELEGRAPHY seems at present to have taken the most important position in the manifestation of the energy of electricity. Telegraphists therefore naturally consider how they can measure the energy with which they deal. If there are any connected with telegraphy present, perhaps they will remember that this is not a lecture on the present advanced state of telegraphy, nor on modern instruments; it is simply an attempt to make as clear to a general audience as is in the lecturer's power the principles which govern the uses and measurements of electricity in relation to telegraphy. To enter into details in reference to those laws which the electrician and mathematician have been enabled to propound, would be not only very injudicious, but very unsatisfactory. A sketch of the broad principles on which they are founded, and an illustration of the application of them, may prove more useful than an attempt to show how details of measurement have been accomplished.

The first question that presents itself is what may be called the measure of resistance. It was soon observed that electricity passed along certain metal wires more freely than other metal wires of the same size and length. The observation admitted of a very important utilisation. For example, suppose the wire now stretched from one end to the other of this room was one mile in length, and that the little apparatus with which electricity is being produced at this end could produce a certain result at the other end. Now, let us take another metallic wire of the same length, and suppose the result produced in this case is much less than in the first. It will be admitted, without any detailed experiment, that by shortening again and again, the second wire may be reduced to a length which permits the phenomenon at the end of the first wire to be repeated at the end of the second. Now measure the second; it is only one quarter of a mile. Try a third and a fourth wire; perhaps they are respectively reduced to one-eighth and one-tenth of a mile. Evidently there is some property in these wires which hinders, retains, or resists the progress of electricity. The property is called "resistance," and is available for very useful purposes. The British Association for the Advancement of Science were so conscious of this that, in 1861 and 1862, there were grave considerations as to what steps should be taken in order to assign a value to this resistance. You have seen how the quantity of electricity may be measured, but then that measured quantity had not to convey itself to a distance. It quietly, as it were, stayed at home and worked. When telegraphy entered then electricity had to travel to or act at a distance. This state of affairs rendered it very desirable to determine "resistance," from what is called first principles, that is to say, to deal only with the three units of measurement, mass, space, and time. It was useful, by some means or other, to get this resistance into the form of mass, space, and time. It was considered that if we could regard it as velocity we thereby involved both space and time, because velocity is measured by space and time. If one runs a mile in an hour, then it is only needful to divide one mile by sixty minutes, and the space run in one minute is known. That would be the measure, assuming the minute to be the unit of time. The British Association appointed a committee. The chief gentlemen concerned in the committee, and who had the designing of a mode of grappling with one of the most critical tasks of science, were Mr. Clerk Maxwell, now Professor of

Physical Science at Cambridge, Mr. Balfour Stewart, of Kew Observatory, now at Manchester, and Mr. Fleeming Jenkin, now Professor of Engineering in the University of Edinburgh. Their experiments were carried on in King's College, and the scheme now to be very briefly described is found in the report of the British Association for 1863.

It may here be remarked that perhaps there have been no lectures ever given in this room of a more important and scientific character than a course of Cantor lectures on electricity by Mr. Fleeming Jenkin. This course commenced in January, 1866, and will be found reported in the *Journals* published between the 2nd February and 2nd March, 1866 (inclusive). It is well to make further statement, that those lectures have frequently been appealed to by writers on electricity who regarded the phenomena thereof in the light of an accurate science.* The question, then, is, how are we to measure in velocity this resistance? How are we to convert that which is resistance in a wire into an electrical measure of velocity? [The lecturer here, by apparatus and diagrams, illustrated the principle upon which this mode of measurement was based, and in so doing referred to the currents passing through the room as already described.] At Kew there is a record of these currents kept continuously night and day, and it is found that they are changing every minute. The main object, then, of the committee of the British Association was to devise a plan by which they could ascertain the resistance that a given wire offers measured by comparison with the velocity of these currents. You may remember that Kater could not measure the law of gravity, owing to the fact that it was rapid in its actions, and he felt that he must have some means of causing that law to repeat itself. Kater adopted the pendulum, and recorded the number of times it oscillated in twenty-four hours, and thereby got at the law. If, instead of having a long wire and three others running along the bar, as in the apparatus before you, we had a ring of this kind, and caused that to revolve rapidly, say at the rate of 100 or 200 or even 1000 revolutions in a minute, we still get the laws of the magnetic force in the same way as described, similar to when the bar passed along the rods before you. This causes the magnetic force to act upon the needle, and in reality, in the experiments which determined what is called "the British Association unit of resistance," these currents acted upon a very small needle carefully suspended, so that they were enabled to estimate the resistance of this wire in an absolute measure of space and time. That led to the adoption of what is called the "ohm," or "British Association's unit of electrical resistance." This term "ohm" is a name given in compliment to one who suggested an important relationship among the elements of current, force, and resistance. Indeed, that table of electrical measurements which may some day be placed in books of arithmetic, with corresponding tables of weights, measures, and money, will be found to contain the names of men who have investigated special departments of electrical science, such, for example, as Ohms, Farads, Volts, Webers, &c.

In this little glass cylinder there is a coiled length of German silver wire, German silver being used because it possesses great resistance to electrical currents, and that resistance does not change much with change of temperature. This coil constitutes what is called half a British Association unit, which becomes the measure of electrical work, just as the standard pound becomes the measure for weight, or the foot is the standard measure for length. Being possessed of this measure, we have all that is needful for the measurement of resistance, and

* Since the commencement of the publication of this course of Cantor lectures, a volume has been issued, entitled "Electricity and Magnetism," by Fleeming Jenkin, published by Longmans and Co., price 3s. 6d. In this volume the author has treated the subject in a novel and a practical manner, very different, indeed, from ordinary text-books on electricity. It will be found to contain matter of great value and interest to the thoughtful student of electricity.

* The Cantor Lectures, delivered before the Society of Arts.

therefore for measuring electrical work connected with telegraphy.*

To show the way in which a knowledge of this measurement can be utilised, rather than to enter upon those investigations by which it was obtained, seemed likely to win so much more attention and interest that these arrangements before you are for this purpose. The intention is to show how electricians determine the distance at which a deep sea cable is broken, so that they can tell how far the fracture is from the shore. Let it be understood that it is the illustration of a principle, and not the nature and modes of dealing with different kinds of "faults," that are to be our concern.

There is a wire, which may represent a cable, round the room. In this box there is placed a number of "ohms" arranged in three sets of nine each, so that by moving these pegs a current of electricity can be caused to pass through either one or more of them. Assuming each "ohm" in the first set to represent one resistance, each in the second set ten, and each in the third set one hundred, the consequence is that, if a current of electricity passes through all, it would meet with a resistance of 999. If it passed through one of the first set, it would only be one resistance; so that, with the moving of these brass pegs, there is the power of bringing in any number of ohms required. This flat board, about 3 ft. 6 ins. long, with a German silver wire and broad bands of copper divided at intervals, but capable of being put into electrical connection by the insertion of pieces of metal, constitutes what may be called the beam of electrical scales. Resistance, however, is to be measured instead of weight. Along a wire at the back, electricity can pass, and, when connected with the galvanometer, the speck of that instrument serves the same purpose as the pointer of a pair of scales. If the galvanometer speck points to nothing, we assume that there is equilibrium between the resistances at each end of the scale beam. If I put 999 "ohms" in what we may call one scale, and other resistances into the other scale, or that which we may consider as such, then, if the current of electricity, arranged as provided, can pass one of these groups of resistances more freely than the other, the speck of light will be moved. This is the same as though one end of a scale beam were "kicked up." Therefore, resistances, which in this case act the part of weights on ordinary scales, must be taken out or added as may be required.

This wire running partially round the room represents a cable. The two ends of this cable are in my hand. Let us assume that we want to measure the resistance the cable opposes to the energy of electricity, and to ascertain the value of its opposing power. Here is what is usually called a battery, consisting simply of a little salt and water, in a very small tumbler glass. "Battery" is a very misleading name in these days. This, with all its belongings, is really not worth sixpence, and it certainly seems a piece of pedantic magniloquence to call it a "battery."

The wires from this battery are so arranged that the current may divide itself between the cable that is round the room and this box of "ohms."

It may perhaps make the illustration more intelligible to those who have not familiarised themselves with terms of electrical science if for a while this current be regarded as consisting of passengers. Let it be represented by 100 passengers setting out from this battery, and having the choice of two routes, viz., one by the cable, and one by this box of ohms.

If the two routes are equally free, i.e., offer equal resistances, then fifty of these passengers will pass by one way and fifty by the other. Suppose that the resistance of one route (say the cable) is greater than that by the other route. Then that other route, or the way through

the box of ohms, will be available for some of those passengers who cannot readily pass by the cable. Here is a wire connecting these two routes; indeed the large letter A may convey a clear idea of the plan. Consider what is likely to happen if fifty of these electrical passengers set off from the top of the A down the thick stroke, and fifty down the thin stroke. We may say that those passing down the thin line cannot pass so freely as those down the thick one. Hence, finding the course down the thick line clear, some of these delayed passengers by the thin line may avail themselves of this cross-wire bridge, viz., the stroke in the A, and go to the place appointed for them by passing down the thick stroke. In this homely illustration the thin stroke is the cable—the thick stroke is the box of ohms. Clearly by moving these brass pegs, the resistance in the box of ohms is increased; that is, the thick stroke of the A is made more nearly the same as the thin stroke. Now introduce into this cross-way—this bye-path, as it were—the galvanometer. Then if any electrical passenger avail himself of this bye-road, the bright speck of light will tell the tale, and by noticing whether the speck moves to the right or left, the direction in which the passenger travelled is known, and therefore the electrical pathway which offers the greatest resistance is also known. By moving the pegs in the box of ohms, an equality of resistance may be established, and then passengers will not pass along the bye-way through the galvanometer; therefore the speck of light will not move.

Nor is this indication of an electrical traveller the only use which may be made of the galvanometer speck. You are aware that the extent of deviation of this needle is the measure of the quantity of electricity in transit; therefore the extent of deviation tells the number of passengers; in fact, the galvanometer becomes an electrical tell-tale turnstile for counting the number passing through, and so indicating or measuring the difference in resistance between the two courses.

Let us leave this figurative mode of expression. In the experiment before you the pegs in the box of ohms read 505; the speck of light is steady; therefore we know that the entire length of cable, of which the two ends are here, also offers a resistance of 505. Before this cable was laid a comparison with these ohms had been instituted, and it was found (say) that one mile of the cable offered a resistance to the passage of electricity equal to one ohm, therefore there are 505 miles of cable, because there are 505 ohms.

Now let us break the cable by cutting the wire. There! one end has fallen to the bottom of this large pan of salt and water. This pan must, for the present, be looked upon as an Atlantic Ocean, one end of the cable is at the bottom of it, and we wish to know how far from the end in my hand the separation has taken place. To compensate for the portion of the cable hitherto used, but now detached, the earth is available; this sheet of copper, in and on the shore of our Atlantic Ocean, is buried. Soldered to the copper is a wire, of which the end is in my hand.

There are therefore in my hands the ends of two wires; one, that of the broken cable—the other, that connected with the buried sheet of copper. Let us deal with them as we did with the complete cable. [After various trials the pegs in the box of ohms were so arranged that the speck of the galvanometer was steady.] The speck is now steady, and the pegs read 350. This means that there are 350 miles of cable, or its equivalent. Now, the cable and the earth are the only elements on the one side; and since the earth is as a large reservoir of electricity it offers no appreciable resistance; hence the only resistance is that of the broken cable. The length of this is pointed out as 350 miles; this, therefore, is the distance of the fracture from the shore.

It is, perhaps, superfluous to state that many circumstances arise differing from those described, and many precautions have to be taken to which no allusion has

* Those who are disposed to give the thought and application requisite for a clear comprehension of these principles of electrical measurement may refer to chapters ix. and x., extending from page 147 to page 165, in Jenkin's "Electricity and Magnetism."

been made. If, however, the general principles be made clear, that is accomplished which was intended to be done, and those who are desirous of further information may consult the higher class of books which treat on practical telegraphy. It may be of some interest to let you see how delicate and perfect a test even this loaded galvanometer speck is. One or two illustrations will show how electrical currents are set in action when we are at least aware of them.

Here is a small piece of zinc, like the blade of a pen-knife, attached to one end of a wire passing round the galvanometer, and here is a piece of copper attached to the other end. The zinc is now pushed into this apple. Observe, the speck moves so soon as the copper enters the apple. Repeat the experiment with a potato; the same phenomenon takes place. The potato forms a very good battery. There is another mode that is really more extraordinary still. If the galvanometer were sensitive, it is no fiction to say you can send a kiss across the Atlantic. Here are two little bits of zinc and copper attached to the ohms and cable combined as one length, and the galvanometer is now in circuit with them. If I kiss these two ends, the speck moves. Therefore, that mysterious something which is called electricity, and which has its origin at the lips, has exerted an energy sufficient to move the needle; indeed, sufficient to travel by the cable from one side of the Atlantic to the other, and move a needle when it arrives there.

Again, here is a small beef-steak and a knife and fork. These latter are connected by two thin copper wires with the galvanometer. One wire is attached to the blade of the knife, and the other to the prong of the silver fork; by watching the speck, you see that even one mouthful of meat cannot be cut without causing a current of electricity quite sufficient to manifest itself on the other side of the Atlantic.

Thus, surrounded by ever-active phenomena, which seem to have escaped the notice of men until the present age, he would indeed be more bold than prudent who ventures to speak confidently of what may or may not be done by one or other of the energies of the imponderables. How novel and delicate are the instruments employed, how accurate are the measurements obtained, and how marvellous are the uses to which electricity has been applied; yet these are not consequences of a blind rule-of-thumb following of that which has been long known. Patient research, persevering labour, and much thought have not only "put a girdle round the earth," but they promise far to enter upon and possess electrical territories of vast extent and luxuriant social fertility. When will the people of England recognise this? Echo answers, "When!"

(To be continued.)

CORRESPONDENCE.

PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—I should like to ask chemists whether they think that the remuneration given to Public Analysts is sufficient in most cases, either to induce men of ability to undertake the duties, or to induce young men at college to study that branch of chemistry with a view of filling the post of Public Analyst. My opinion is that it is not; the fees and salaries paid, either or both, as the case may be, are miserably low in the extreme; and no man could undertake the duties who has not other means of making a comfortable living, and such being the case it is evident that he can give but a small portion of his time to the duties connected with his office. Hoping to hear the opinions of some experienced chemists,—I am, &c.,

P. S. G.

ALUM IN BREAD.

To the Editor of the Chemical News.

SIR,—In an editorial postscript to a letter in the CHEMICAL NEWS, vol. xxviii., p. 262, you promise an article on the detection of alum in bread. As in the letter to which your note is appended reference is made to what is termed the "Shoreditch Case," I trust that you will not hastily assume the truth of the incorrectly-reported, and *ex parte* statements which have been published of the proceedings at the Shoreditch Vestry with respect to the analysis of bread.

Till the Select Committee has reported on the allegations made against me, I may fairly assert that no *proof* has been as yet forthcoming that I have had any bread adulterated with alum sent to me for analysis from Shoreditch.—I am, &c.,

THE SHOREDITCH ANALYST.

November 22, 1873.

[We have also received a letter from Prof. Gardner on this subject, which, however, arrived too late for publication.]

IRON IN TEA.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS, vol. xxviii., p. 259, there appeared an article by Mr. W. Mattieu Williams on "Iron Filings in Tea," and as a public analyst who has devoted some attention to the tea question, I regret that I differ materially from Mr. Williams on some points.

It appears to me that your correspondent has formed his opinion wholly from what he has read, and has not personally examined any of the so-called "iron filings" from tea. I have come across several specimens of tea containing genuine iron filings, soluble in nitric acid with effervescence (magnetic oxide is scarcely soluble in nitric acid), and in one instance found real *lumps* of metal.

Thus it is a mistake to suppose that the metal is always introduced as *filings*, and I am surprised that Mr. Williams, with his Sheffield experience, should lay so much stress on the trouble of obtaining finely-divided iron. I have no doubt I could beg a hundredweight to-morrow. Still there is little doubt that in some instances the magnetic matter has consisted of the native oxide, and I have at the present time a tea under examination which contains the iron in this very form. But, remembering the refractory character of native magnetite or hæmatite, it seems very improbable that it would be appreciably acted on by a weak vegetable acid like tannic acid, though the hydrate formed by the rusting of introduced metal would readily react.

But the difficulty of introducing iron filings or borings is considerably over-rated. If it pays to introduce from 3 to 8 per cent of quartz pebbles, as large as the V of the "VOL." on the title-page of the CHEMICAL NEWS, and to roll them up in the interior of tea leaves, as seems to be the usual practice with low-class "capers," it would surely answer with iron, which has a higher specific gravity and possibly some chemical action. We can understand the tea plant to become dusty, as our gooseberry and currant bushes do in England, but that 5 per cent of little stones could adhere to the leaves throughout the process of picking is incomprehensible.

Mr. Williams appears to consider that an addition of 5 per cent of a substance not injurious to health ought not to be considered an adulteration. But if a half-crown tea contain 5 per cent of stones, the purchaser pays 1½d. for rubbish, and is certainly defrauded to that amount. In many businesses the seller is content with 5 per cent profit.

But the iron is not always present in the metallic state or in the condition of native oxide. In several instances I have found considerable quantities of soluble iron com-

pounds, no doubt added as a "dye," as Mr. Williams would probably call it. Now the popular judgment of the strength of a tea being founded on the depth of colour possessed by the infusion, the effect of the addition of sulphate of iron is to give the tea a fictitious strength, and seems as unjustifiable an addition as that of cayenne to give a sulphuric acid to vinegar. In addition to this, the habitual drinking of strong chalybeate water is very unsuitable to most constitutions.

It is usual to credit the Chinese with the adulteration of tea, but I am much inclined to think that in some instances we should look nearer home.

The addition of sulphate of iron to tea is an adulteration of so eminently scientific a character that one is led to suspect the "dye" to have belonged to a nation more highly civilised and alive to the advantages of applied science than the "Heathen Chinee" is generally supposed to be.

The difficulties which public analysts have had to contend with have been very considerable, owing to the want of definite and reliable processes for the detection of certain adulterations of tea, and the absence of sufficient data as to the composition of genuine teas.

Mr. Wanklyn has given us valuable information as to the ash of tea, and I have myself obtained more exact determinations of the percentage of tannin and theine, and so, as the necessity arises, the other doubtful points will no doubt find a solution; but during the attainment of analytical perfection the want of more definite information will prevent the detection of many cases of adulteration, and thus give a dishonest tea-dealer the advantage.

It is certainly much to be regretted that so many of the analysts appointed under the new Act are men to whom it would be useless to look for help in the elucidation of obscure questions, and it seems that we may even have bungling in cases where a mistake appeared impossible; but I think if chemists will look back on the work of the past year, they will find that the public analysts have given them valuable original information on many points, including milk, butter, and tea.—I am, &c.,

ALFRED H. ALLEN.

Borough Analysts' Laboratory,
Sheffield.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of sulphate of soda and sulphate of potassa. James Hargreaves, Widnes, Lancaster, chemist, and Thomas Robinson, iron founder, of the same place. February 22, 1873.—No. 680. This relates to the production of sulphates by our direct action method. (1.) Sulphates are mixed with the chlorides previous to the mass being broken into pieces. (2.) Solutions of salts of copper, zinc, manganese, or chromium, are added to the chlorides, preferably before the mass is dried, and broken into pieces. (3.) Steam or atmospheric air is employed to displace the gases contained amongst the converted finished sulphate.

Improvements in the purification of syrups and sugar. Alexander Melville Clark, patent agent, 53, Chancery Lane, Middlesex. (A communication from Louis Joseph Frédéric Margueritte, of Paris.) February 22, 1873.—No. 682. The invention relates:—(1.) To the purification of syrups from beet-root, cane, or other sugar, by the action of acids on the saccharine juices in a boiling state, either in a vacuum or otherwise. (2.) To the treatment of saccharine juices for extracting crystallisable sugar therefrom, preferably by the aid of sulphuric or hydrochloric acid, by boiling in a vacuum at a low temperature. (3.) To the use of like means for purifying molasses. (4.) To improving first, second, and third quality sugars by like means.

Improvements in the composition of artificial marbles, stones, and cements of every kind, in making them firmer, harder, less absorbent, and more able to bear exposure to air, water, and other influences, than hitherto, which improvements are applicable to the making of paints, and as a substitute for leather and other like fabrics. Samuel Rowbotham, operative chemist, 24, Leighton Road, Kentish Town, London, and George Richardson, Chignal Hall, Chignal St. James, near Chelmsford, Essex. February 24, 1873.—No. 684. The use of albumen in mixing with plastic, of parts or other substances, and its coagulation by heat, or by any other means capable of effecting such coagulation.

An improved method of obtaining photometric measurements, and apparatus for that purpose. Major Francis John Bolton, 21, Grosvenor Mansions, Westminster, Middlesex, and Major Charles Edmund

Webber, R.E., 91, Cornwall Gardens, Kensaington, Middlesex. February 24, 1873.—No. 686. This invention relates to a method of and apparatus for obtaining photometric measurements in terms of electrical measurement. A body, of which the electrical conductivity or resistance is altered by exposure to light, is placed in an electrical circuit, in which circuit is also placed an electrometer or gauge of electrical resistance. Light is directed on the body, and the value of this light, or the transparency or density of any translucent substance through which the light is passed is tested by the effect on the electrometer or resistance gauge.

Improvements in boiling wood or other fibrous material for the manufacture of paper, and in the treatment of the waste lyes. James Abraham Lee, Severn Engineering Works, Lydney, Gloucester. February 24, 1873.—No. 695. This Provisional Specification describes the use of an exhaust pump to discharge the air contained in the material, and so replacing it with caustic solution. Also the addition to spent lye of acetic acid to form a valuable product and solid residue. Also the addition to spent lye of other acids, with a similar object.

An improvement in the manufacture of candles, matches, and other like articles, together with a lamp or apparatus for burning such candles. Alexander Melville Clark, patent agent, 53, Chancery Lane, Middlesex. (A communication from W. J. S. Grawitz, Paris.) February 25, 1873.—No. 703. This invention relates to the application of naphthalene—

(1.) As a substitute for sulphur, wax, resin, or other inflammable materials used for dipping or impregnating matches and firelighters. (2.) As an addition to the phosphorus paste in which the ends of wax and other matches are dipped. (3.) To increase the inflammability of candles, tapers, links, and torches. (4.) For burning in lamps in the form of a hollow candle, provided with an independent wick and double air current, the flame serving to melt the solid naphthalene to feed the wick.

An improved mode or process of preserving meat. Eugène Metzger, and Félix Nicolas Cyprien Vuibert, both of Boulogne-sur-Mer, France. February 26, 1873.—No. 710. This invention relates to a method or process of preserving meat in bulk in its fresh, uncooked condition. The animal is killed by felling, and immediately skinned and cleaned. It is then glazed over with a preparation of sugar and alcohol and placed in a case in a bed of fat. The case is exhausted of air and soldered up.

Improvements in the manufacture of size. Robert Kay Whitehead, bleacher, Walmerley, near Bury, Lancaster. February 28, 1873.—No. 743. The object of my invention is to prevent mildew in yarns, woven fabrics, and other fibrous substances or materials, and it consists in combining a certain quantity of mustard oil or other vegetable oil possessing similar antiseptic properties, with the farinaceous or other size, which is applied to the yarns, woven fabrics, or other fibrous substances or materials for the purpose of stiffening them.

An improved artificial fuel. Thomas Cadett, Rosherville, Kent. February 28, 1873.—No. 744. Peat, turf, or bog is combined either with tar, pitch, resin, asphaltum, or other resinous or bituminous substance, or with oil. The peat or turf is first dried by exposure or by artificial heat, and is then immersed in one or other of the above substances and submitted to pressure in moulds, to thoroughly impregnate it with the tar or other substance and express any superfluity. After being again dried it is fit for use.

NOTES AND QUERIES.

Removing Black Dye.—If any of your subscribers could give me the best and cheapest way to remove the black dye from worsted that has been dyed black, they would confer a favour.—A. Z.

Orchil.—I should be very glad if any of your correspondents could favour us readers of the CHEMICAL NEWS with an article on the manufacture of orchil. I have taken your valuable paper a long time now, and have never seen it mentioned. It is becoming an important manufacture in Leeds, for in 1860 there were only three works, and now there are eight works, employing nearly 200 hands.—A POOR WORKING LAD STRUGGLING FOR INFORMATION.

The Estimation of Sulphur in Pig-Iron.—In the explanation of the "simple and ready" method described by me in the CHEMICAL NEWS, vol. xxviii., p. 248, I do not perceive any claim to absolute originality; but that it was worthy of note is proved by the fact that it found place in the columns of the CHEMICAL NEWS. Persons using chemical processes by rule-of-thumb, as is generally the case in metallurgical laboratories, probably do not test the purity of their reagents, from whence, doubtless, arises the discordance of their results.—CHARLES H. PIESSE.

SUPPLEMENT TO THE CHEMICAL NEWS.

VOL. XXVIII. No. 731.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 20, 1873.

Dr. ODLING, F.R.S., President, in the Chair.

THE names of the visitors having been announced, and the minutes of the previous meeting read and confirmed, Messrs. John Turner and G. Bulk Francis were formally admitted Fellows of the Society.

The following names were read for the first time—Messrs. Edward H. Davies, Sydney Trivick, John Smyth, M.A., Edmund Richard Southby, Edward Daniel Stone, John Sutherland, Carl Schorlemmer, F.R.S., and John Clement Smith.

For the third time—John Douglas, Esq., who was ballotted for and duly elected.

The first paper, "*On the Coefficient of Expansion of Carbon Disulphide*," by J. B. HANNAY, was then read by the Secretary. It contains the results of a numerous series of determinations of the specific gravity of carbon disulphide at small differences of temperature made in an apparatus of peculiar construction, so as to prevent evaporation, and to admit of the subsequent expansion of the liquid when adjusted at low temperatures. When the apparatus was carefully cleaned, the disulphide could be heated in it considerably above its boiling-point, thus affording a means of obtaining its specific gravity at comparatively high temperatures. The temperature of the specific-gravity bulbs was adjusted by immersing them in water kept at a constant temperature by a modified form of Carmichael's apparatus. Two tables of the calculated and observed variation from 0° to 62° C. in the volume and specific gravity of the disulphide, the latter referred to water at 4°, accompany the paper. From the results the author concludes that carbon disulphide expands equally for each equal increment of temperature, the number denoting the coefficient of expansion being 0.001129, and that denoting the decrease of specific gravity 0.001461 for each degree Centigrade.

THE PRESIDENT said the thanks of the Society were due to the author for his communication, and also for the new form of specific-gravity bottle he had introduced to their notice.

Dr. MILLS remarked that, if the coefficient of expansion of carbon disulphide were the same for a considerable range of temperature, it would differ in that respect from every known liquid, as their expansion was represented by a function of the third degree. The speaker had had some experience in working with delicate thermometers, and would like to ask how the temperature was determined. It was well known that the zero point of new instruments varied considerably from day to day, so that, although an accurate determination might be made with the corrected thermometer to-day, at the end of a week there might be a comparatively large error if the same correction were employed. In determinations giving such abnormal and extraordinary results, the details of the thermometric corrections should be given.

Professor G. C. FOSTER pointed out that the author had stated that the specific gravity of the liquid diminished by a constant number for each equal increment of temperature; now, if this were true, it was obvious that equal decrements of specific gravity would not give equal increments of

volume, and it was therefore impossible that the expansion should be constant; there must be some error in the calculations.

THE SECRETARY said no details were given in the paper of the precautions taken in determining the temperature.

A paper, "*On the Action of Hydrogen on Silver Nitrate*," was then read by the author, Dr. RUSSELL, F.R.S. He finds that thoroughly washed and purified hydrogen causes a precipitate of metallic silver from a solution of silver nitrate, the precipitation occurring much more readily in saturated than in dilute solutions. The gas employed was usually procured by the action of a saturated solution of copper sulphate on zinc, or by the action of water on a mixture of powdered zinc and tin; after it had been passed for about half an hour through a saturated solution of the silver salt, a dull greyish deposit is produced, which is succeeded by a bright crystalline precipitate. This precipitation is quite independent of the action of light, but is increased by heat; a clear solution, through which hydrogen had been passed for a minute, became turbid, and gave a precipitate of silver when heated. Similar effects were obtained when the solution was exposed to an atmosphere of hydrogen, instead of causing the gas to bubble through it. The author has conclusively proved that these phenomena are caused by the hydrogen displacing the silver in the silver nitrate, producing hydric nitrate, but a secondary reaction also takes place between the nitric acid and the precipitated silver, resulting in the formation of silver nitrite, and, as silver nitrite is not decomposed by hydrogen, the end product formed would be silver nitrite. Dilute solutions of nitric acid have little or no action on metallic silver, so that hydrogen precipitates silver as readily in a solution containing 7 per cent of nitric acid as from an aqueous solution; on the contrary, even very dilute nitric acid, if it contains a trace of nitrous acid, readily dissolves the metal. Platinum, palladium, and gold are completely precipitated from their solutions by hydrogen. Copper nitrate is reduced to nitrite, whilst mercuric nitrate deposits a basic nitrate.

Dr. ODLING thanked the author for the very complete manner in which he had investigated this subject of the precipitation of silver by hydrogen.

Professor MASKELYNE said the experiments of Dr. Russell were particularly interesting to mineralogists, and might throw some light on the relation between the circumstances under which the substance was precipitated and its crystalline form, as it was far easier to ascertain facts than to give satisfactory explanation of them; for instance, why did sulphate of barium occur in a particular district crystallised in one set of forms, and in another district in another set of forms? In order to get some insight into this matter, the conditions of the formation of crystals must be carefully observed. He had examined the crystals of silver, and found them to be octahedra; the filamentous form consisted of chains of octahedra.

Dr. C. R. A. WRIGHT had listened to the paper with great interest; when endeavouring to determine the sulphur in iron, by dissolving it in acids, and passing the evolved gas through various metallic solutions—and, amongst others, ammoniacal nitrate of silver,—he had found more silver was precipitated than corresponded to the sulphur in the iron. He would like to ask Dr. Russell whether he had tried the action of hydrogen either on ammoniacal silver nitrate or on the solid nitrate itself.

Professor WILLIAMSON said there was a point of some interest connected with the paper—namely, as to hydrogen being more soluble in a solution of silver nitrate than in pure water. According to Dr. Russell, about half an hour elapsed before the silver began to be precipitated, so that there might be time to ascertain the amount of hydrogen dissolved. As the solubility of hydrogen in water diminishes with rise of temperature, it was conceivable that hydrogen also dissolves less freely in hot solution of silver nitrate than when cold. This would afford an explanation of the precipitation of silver from the solution when it was heated. Supposing the silver is only precipitated when

the solution is saturated with hydrogen, the cold solution, not being saturated, would give no precipitate, but, on heating it, silver would be precipitated as soon as the saturation-point was reached.

Dr. RUSSELL replied that he had not as yet made any determinations of the solubility of hydrogen in nitrate of silver solution. He had also forgotten to say that he had found that, when air was excluded, the product of the action of silver on nitric acid was silver nitrite.

Dr. C. R. A. WRIGHT read a "Note on the Action of Zinc Chloride on Codeine." In attempting to prepare apocodeine for the market, according to the process of Matthiessen and Burnside, by acting on codeine with zinc chloride, Mr. D. Brown obtained a product which possessed most of the properties ascribed to apocodeine hydrochloride, but which, when analysed by the speaker, was found to be isomeric with codeine hydrochloride; in fact, at low temperatures, the chief product is a loose compound of zinc chloride with the hydrochloride of the base *tricodeine*, and, if a longer time of heating be adopted, or a higher temperature, *tetracodeine* is also formed. The author thinks that Matthiessen and Burnside's apocodeine was an alteration product, due to the action of hydrochloric acid on the tricodeine first formed.

Dr. ODLING having thanked the author for his communication, a memoir "On the Chemical Properties of Ammoniated Ammonia Nitrate," by E. DIVERS, M.D., was read by the Secretary. In this paper the author describes the action of the liquid produced by the deliquescence of ammonia nitrate in an atmosphere of dry ammonia on various elements and compounds, comparing the results with those obtained by Gore with ammonia liquefied by pressure. As a rule, these properties appear to be the result of the joint action of the two constituents of the liquid—namely, ammonia and ammonia nitrate; the latter, as might be expected, considerably modifying the action of the ammonia. The behaviour of the liquid towards upwards of 150 substances was examined, including most of the elements, the metallic chlorides, oxides, and sulphides, also some bromides, iodides, nitrates, carbonates, chromates, &c.

The PRESIDENT having thanked the author in the name of the Society, a note "On the Analysis of a Meteoric Stone, and the Detection of Vanadium in it," by R. APJOHN, was read by the Secretary. After alluding to former analyses of meteoric stones, and enumerating the elementary bodies present in them, the author draws attention to the fact that the proximate constituents of meteorites are generally the same as those of trap-rocks, and, since vanadium is found in the latter, it might possibly also exist in the former. An examination of a meteoric stone which fell, in 1870, in the county of Limerick, showed that it contained vanadium. A complete analysis of the stone is given, and the analytical methods employed are described in detail.

After returning thanks to the author, the PRESIDENT finally adjourned the meeting until Thursday next, Dec. 4.

MISCELLANEOUS.

Exhibition of Appliances for the Economic Consumption of Fuel.—Practical and scientific inventions and improvements of all kinds bearing on the solution of the great fuel question are to be afforded the fullest scope for treatment at the forthcoming Exhibition of Fuel-Economising Appliances, to be held by the Society for the Promotion of Scientific Industry. The following comprehensive classes of exhibits are now announced by the Council of the Society:—(1). Appliances which may be adapted to existing furnaces, &c., whereby an improved combustion of the fuel is secured, and a direct diminution in the quantity required is effected. (2). Appliances which may be adapted to existing steam boilers, &c., whereby the waste heat of the flue gases or of exhaust steam is utilised, (3). Appliances which may be adapted to existing steam-

boilers, pipes, and engines, whereby loss of heat from radiation and conduction is prevented. (4). Appliances which may be adapted to existing steam-boilers and engines, enabling them with safety to realise the great economy resulting from the use of high-pressure steam or superheated steam. (5). New or improved furnaces (using solid, liquid, or gaseous fuel), boilers, and engines of all descriptions, specially adapted for the saving of fuel. (6). Apparatus which, by producing a cheap and abundant gaseous fuel, will supersede the costly carriage of coal, obviate the present enormous waste attending its use in the solid form, and condense and save the valuable sulphur, ammonia, and other by-products of the distillation, now injuriously affecting iron- and other smelting processes, and, in a vast number of operations, discharged as poisons into the air. (7). Apparatus or engines for obtaining power advantageously from heat through any other medium than steam. (8). Natural and artificial fuels of all kinds. (9). Coal-cutting machines; peat-manufacturing machines. (10). Domestic and other fires, stoves, ranges, and apparatus of all kinds (using coal, gas, or other fuel) for cooking, and for warming rooms and buildings. (11). Mechanical or other arrangements for securing the delivery of proved weights of fuel to the domestic consumer. The Exhibition is to be held in Manchester, and will be opened on December 18th, by the Rt. Hon. the Earl of Derby, F.R.S., President of the Society. In consequence of the large amount of space that has been applied for, the Council of the Society has determined to increase the size of the Exhibition Building, and to include the appliances named in 9, 10, and 11 as above.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 20, 1873.

Production of Certain Crystallised Borates by the Dry Way.—M. A. DITTE.—(Continued from page 783.) The author has formed and examined the biorate of baryta, $\text{BaO}, 2\text{BoO}_3$, containing—

Baryta	52.37
Boracic acid	47.63

100.00

and also the sesquiborate, $2\text{BaO}, 3\text{BoO}_3$, which contains—

Baryta	58.46
Boracic acid	41.54

100.00

A magnesium salt was obtained, containing—

Magnesia	30.00
Boracic acid	70.00

100.00

and answering to the formula, $3\text{MgO}, 4\text{BoO}_3$, which corresponds exactly to that of the native boracite of Brunswick occurring in the gypsum which forms interposed masses in the chalk formations. Another compound obtained, $3\text{MgO}, 2\text{BoO}_3$, is analogous to the basic borates of strontia and lime. The neutral salt, MgO, BoO_3 , contains—

Magnesia	36.85
Boracic acid	63.15

The author also obtained certain double borates, as a double

borate of lime and magnesia, $(3\text{CaO}, 2\text{BoO}_3)(3\text{MgO}, 2\text{BoO}_3)$. A double borate of strontia and magnesia was found to have the composition, $(3\text{SrO}, 2\text{BoO}_3)(3\text{MgO}, 2\text{BoO}_3)$. The analogous barytic compound was not obtained.

Chloro-Vanadates.—M. P. Hautefeuille.—The reproduction of vanadinite, and the preparation of a Wagnerite containing vanadium, have enabled the author to show that the vanadates, like the phosphates and the arseniates, form two series of isomorphous salts in combination with chlorides. Vanadinite was formed by heating to dull redness pure vanadic acid intimately mixed with litharge, and with a large excess of lead chloride. After cooling and dissolving out the chloride of lead we obtain yellow transparent needles of a fatty lustre. These crystals, like the natural product, contain 3 equivalents vanadate of lead to 1 of chloride. The chlorides capable of uniting with the vanadates when fused are not numerous, the greater part being decomposed by vanadic acid. This is the case with the chloride of magnesium. The chloride of calcium, on the other hand, forms a chloro-vanadate of lime if heated moderately with the needful ingredients. It forms, when freed from excess of chloride of calcium, crystals of a dead white, and of an adamantine lustre. They contain—

Vanadic acid	39.07	1 equiv.
Lime	36.66	3 "
Chloride of calcium .. .	23.75	1 "
Loss	0.52	

100.00

This salt, when crystallised, does not belong to the same type as vanadinite; it is not an apatite, but has the composition of the wagnerites, containing equal equivalents of vanadate and of chloride.

Mode of Producing Methylamins in the Manufacture of Pyroligneous Products.—M. C. Vincent.—Crude pyroligneous acid saturated with slaked lime before the separation of the methylic alcohol, and submitted to partial distillation, yields crude methylic alcohol; the first portions of which contain ammonia in considerable quantities, and some traces of methylamin. This alcohol, completely saturated with sulphuric acid, deposits a white, crystalline, non-deliquescent mass, insoluble in methylic alcohol, and readily crystallisable from water. If, instead of immediately collecting the alkaline methylic alcohol, it is submitted to rectification in an apparatus furnished with a cohobator, we obtain a product the first portions of which are rendered alkaline by a small quantity of ammonia, and a notable amount of methylamin. This alcohol, re-distilled several times in the same apparatus, contains only traces of ammonia; but, instead, considerable quantities of methylamin, dimethylamin, and trimethylamin.

Theorem Relative to the Movement of a Point Attracted Towards a Fixed Centre.—M. Bertrand.

"Astronomische Mittheilungen" of Dr. Rudolphe Wolf.—M. Faye.—The connection of sun spots with magnetic variations is made very obvious in this work. With the aid of fellow-workers in Switzerland, Germany, Italy, and Greece Dr. Wolf determines, for every day in the year, the number measuring the frequency of the spots. From these numbers he can calculate the variations of declination of the needle at a given point on the earth's surface when two constants have once been determined for the place (as in calculation of tides). Thus, take Batavia, the constants are 2.130 , and 0.0185 ; the number, R , of the spots is connected with the variation in declination by the simple formula, $\varphi = 2.130' + 0.0185' R$. From a list of the variations as observed, and, as calculated from the spots, it appears that the average divergence (in 1868-9) is only about $\pm 3''$. Dr. Wolf's observations justify the expression "cosmic meteorology."

Explanation of Solar Spots Proposed by Professor Reye, of Strasburg.—M. Faye.—Dr. Reye considers that waterspouts and cyclones are exactly the same kind

of phenomena as the small whirlwinds in our streets. They are due to the ascent of the lower layers of air when the vertical decrease of the temperature has become such as to render the equilibrium of the atmosphere unstable. Then the least accident will cause, here or there, the ascent of a puff; and once the movement has commenced the air of the lower layer flows towards this point. By the narrow orifice considerable masses then arise from all sides, widening more and more (upwards) the channel of ascent. The lower hot air, dilating in the upper regions, has part of its vapour condensed, and the heat due to this condensation, rendering it still lighter, adds to its ascensional force. Then, as to sun spots, Dr. Reye's view is that when a facula forms on the solar surface the extreme heat from it causes, in a limited region of the photosphere, the following phenomena:—The temperature of the atmospheric layer immediately resting on the facula rises, and renders the equilibrium unstable. The mass of gas and vapours composing this layer tends to rise into the upper layers. There may then be formed above the facula a sort of waterspout (*trombe*). The cooling which results causes condensation of vapours, and produces within the opacity necessary to mask the subjacent region of the atmosphere. This cloud may be 100 or 200 German miles in height. Below it, and laterally, gaseous masses will escape in conical sheets. Already partially deprived of this vapour, these will deposit much higher a number of small opaque clouds, which will form the penumbra. At length this gaseous mass, quite deprived of vapours by successive condensations, will play violently above the chromosphere and outside of the penumbra in flames of nearly pure hydrogen. Dr. Reye does not dispute Wilson's celebrated observation that the spots are cavities, but he urges that this observation is as well satisfied with funnels situated above the sun, as with funnels situated in its very mass. On this M. Faye remarks as follows:—Suppose a circular vessel in the middle of a table to be viewed obliquely by an observer too far off to have perception of relief. He is required to decide whether the vessel is simply placed on the table, or inserted in a circular hole such that the whole body of the vessel is under the surface. He will perceive two ellipses which are not concentric. Now he can, by measuring on the perspective tableau the distance from the bottom of the vessel to two opposite edges, decide the question. If these distances are equal the vessel is exterior to the table; if the distance from the bottom of the vessel to the table-edge next the observer is the smaller, the vessel is inserted in the table. This principle, applied in solar measurements by Mr. Carrington, has shown that the cavity of the spot is always in the body of the sun. A second method is that of considering the upper orifice of the penumbra; and P. Secchi has found that the centre of this orifice does not undergo displacement, whatever its distance from the centre of the sun. Hence, the upper orifice must be level with the photosphere, and not 900 or 1000 German miles above it. A third and still more simple method is that of a sectional view. The vertical ascending "waterspouts" when they reach the border should be visible and brilliant during total eclipses. But it is not so. Besides, at ordinary times, the spots are observed to disappear at the border like simple holes, without indication of relief. All tends to show that the spots are not without the sun in its atmosphere, but in the thickness of its brilliant mass.

Easy Method of Measuring the Capacity of Ships.—M. D'Avert.

Production of Galls on Vines Attacked by Phylloxera.—M. Max Cornu.

Reproduction of Phylloxera Quercus.—M. Balbiani.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, October 27, 1873.

Action of Formiate of Soda upon Sulpho-Benzic and Benzoic Acids.—V. Meyer.—The author shows that

when formiate of soda acts upon sulpho-benzoate of potassa in the manner which he adopted no terephthalic is formed. Sulpho-benzoic acid is converted by formiate of soda into isophthalic acid, in circumstances in which no aromatic dicarbon acid arises from benzoic acid. Hence he concludes that the isophthalic acid formed on fusing sulpho-benzoate of potash with formiate of soda arises from the direct replacement of the sulpho group by carboxyl, and not from the benzoic acid re-formed in the reaction.

Constitution of the Benzoic Series.—Victor Meyer.—The author observes that no chemist will seriously maintain that the constitution of any chemical compound has been established with absolute certainty.

Decomposition Products of Bichlorpropionic Ether and Amide by means of Lime.—A. Klimentko.—The author declares that his results are as yet insufficient even for a preliminary notice.

Utilisation of Platinum Residues.—Th. Knösel.—The author communicates a process for preparing chloride of platinum from platinum residues, and from the alcoholic washings. The precipitates are placed in a porcelain capsule, and are mixed with caustic soda, heated upon the water-bath, and the alcoholic washings gradually added. The reduction is rapid, and the metallic platinum is deposited in a spongy state. The reduction is at an end when the supernatant liquid appears almost colourless. It never becomes quite colourless, on account of the formation of certain organic compounds which impart a faint yellow tinge. The metallic platinum is repeatedly washed by decantation with boiling water, and then washed upon the filter till the reaction of chlorine disappears. It is then dried, heated to redness, and is then ready for further treatment. It is boiled in hydrochloric acid to remove impurities, and then dissolved in aqua regia, preferably in the water-bath. The chloride of platinum is repeatedly evaporated to dryness, and re-dissolved in boiling water to remove nitrous acid. Finally, the solution is bleached in direct sunlight.

Certain Constituents of Poplar Buds.—J. Pickard.—The author corrects certain typographical errors in his communication in No. 13.

Revolution in the Soda Manufacture.—Rudolf Wagner.—The author gives the history of the gradual development of the "ammonia process," and a view of its advantages.

New Hydrate of Quinine.—A. C. Oudemans, jun.—The author found two samples of quinine containing 9 equivalents of water of hydration instead of 3, but was unable to explain their formation.

Molecular Deflecting Power of Tartaric Acid and its Salts.—A. C. Oudemans, jun.—A critique on Landolt's paper (*Berichte*, vi. p. 1072).

Nitro-Compounds of the Fatty Series.—Victor Meyer and C. Wurster.—The authors examine the action of sulphuric acid—both fuming and ordinary—upon nitro-ethan, and also that of alcoholic potassa.

Peroxides of Barium, Strontium, and Calcium.—Remarks upon Mr. Convoys's paper (read before the London Chemical Society, June 5), with whose results the author generally agrees.

Communications from the Odessa Laboratory.—W. Markownikoff.—The author describes the conversion of diæthoxalic acid into diæthyl-acetic acid, the formation of polymeric isobutyl-aldehyd, the properties of cetone, and some methods of forming the compound ethers.

On Cyanide of Thallium.—C. Frommüller.—The author found that the cyanide of thallium is readily soluble in water; easily decomposed by the carbonic acid of the air; that its aqueous solution is completely decomposed even in the absence of air; and that the compound cannot exist in the dry state at low redness. He obtained the cyanide by mixing a saturated and boiling solution of sulphate of thallium with its equivalent of a boiling saturated

solution of baryta, and filtering off the sulphate of baryta in a flask. When cold the solution of protoxide of thallium is mixed with an excess of concentrated prussic acid. After agitation alcohol is added in excess, and as much ether as will dissolve in the liquid. A heavy, amorphous, white precipitate falls down. It is freed from the mother-liquor by decantation, washed with a mixture of alcohol and ether, and dried under the air-pump. Its composition is—

Thallium	88.69
Carbon	5.21
Nitrogen	6.08

99.98

The solution of cyanide of thallium dissolves the cyanides of silver and zinc, forming double salts much more stable than pure cyanide of thallium.

Alizarin as an Indicator in Titration.—Eugen Schaal.—The author finds that alizarin is far more sensitive than litmus, so that it shows distinctly $\frac{1}{100000}$ of alkali, whilst a neutral solution of alizarin, strongly diluted, is coloured yellow by 0.0007 of hydrochloric acid. The author prepares his solution of alizarin by dissolving this substance in boiling potassa lye with a drop of carbolic acid, and filtering in the cold. The neutralisation of acidity is marked by a change from yellow to rose colour.

Various Communications.—F. Beilstein and A. Kupfer.—The authors treat of the cymols of the oil of carraway, and of camphor; of cymol-sulphuric acid and its salts; of the oil of wormwood and its product, absinthol; on cumic acid and its salts, and on the metallic derivatives of cyanamid.

Investigation of Cholic Acid.—F. Baumstark.—The author examines cholic-ethylic ether, cholamid, and cholic-benzoyl-ethylic ether. He finds that diæthyllic acid corresponds to choloidinic acid, and lactic to the product of the dry distillation of cholic acid.

Diphenyl-Acetic Acid and Benzilic Acid.—R. Symons and Th. Zincke.—The authors examine the diphenyl-acetates of barium, calcium, zinc, and silver, and its ethylic ether. They consider it proved by their results that benzilic acid has the formula ascribed to it by Staedeler.

Synthesis of Tauro-Carbaminic Acid.—E. Salkowski.—On leaving in contact taurin and cyanate of potash in equivalent proportions the mixture deliquesced at first, and in two days was resolved into a crystalline mass—the tauro-carbaminic acid of potassa.

Reimann's Färber Zeitung, No. 42, 1873.

This number contains a receipt for a logwood-blue on wool, which bears soap and, to a slight extent, fulling. 50 lbs. of wool are boiled for an hour with 1 lb. of yellow chromate of potash, 5 ozs. of sulphate of copper, and 10 ozs. of sulphuric acid, and allowed to lie overnight in the decoction. The next morning it is dyed in a fresh bath with 5 lbs. of logwood, 3 lbs. of prepared tartar, and 4 to 4½ lbs. of the coarsest neutral extract of indigo.

There follow receipts for a dark green on fine wools; a dark green on inferior goods; a Russian green; a vat green on wool; a drab-grey on old silks; a reseda on old silks; a brown on mixed goods; a red and white (printing) on a black ground; a pansy and a maize on silk; an olive; a reddish Havana and a yellowish Havana on plush; a chamois; crimson II.; crimson I.; rose III., II., and I. on wool (printing); and a ponceau on shoddy.

Discovery of Artificial Alizarin.—The original idea is assigned to Strecker, and to Graebe and Liebermann the honour of its practical execution.

Royal Institution.—At the General Monthly Meeting, to be held at 2 o'clock on Monday, December 1, a President will be elected in the room of Sir Henry Holland, Bart., M.D., D.C.L., deceased.

THE CHEMICAL NEWS

VOL. XXVIII. No. 732.

A DISCOURSE ON ATOMS.

I SEE that some chemists are giving themselves a good deal of trouble by discussing the atomic theory without distinguishing between that of Leucippus and that of Dalton.

The first is open to discussion, and will long be. We must learn much concerning matter before we can say with certainty that it consists *primarily* of indivisible particles or atoms.

The second—namely, the theory of Dalton—is not, in my opinion, open to discussion, simply because no one has yet opened a door sufficiently large for a doubt to enter by. Is this a mere matter of opinion? So far as I see, it is not, and all chemists confirm it in practice, willingly or unwillingly.

Now why should one theory be doubtful, and the other not doubtful? The reason is clear enough to the writer, but it remains to be seen whether it will be clear enough to all. It is this. The physical atoms of Leucippus and his school are the least possible divisions of matter, or, if you please, the smallest created or existing parts. The atoms of Dalton are not necessarily so. They are only the smallest of which we may be said by reasoning on our experiments to know anything, and they may be for all we know, and they probably are, compound molecules. The atoms of Leucippus are indivisible according to theory; the atoms of Dalton are indivisible by our chemistry. As such, and as such only, can we view the atoms of Dalton. Dalton's theory is an expression of the facts of the science of chemistry, but the atoms of Leucippus, and Epicurus, Lucretius, Newton, and even Dalton himself, considered as a physicist, are no help to us. The Greek atom is still undivisible; the Daltonian is undivided.

Let us take a drop of water, and divide it as far as Nature ever divides it, and it still contains oxygen and hydrogen. Let us divide it as much as you can imagine it divided, and still it contains oxygen and hydrogen; you cannot even conceive a piece so small that it shall not contain these two elements. Yet it is an atom of water—one indivisible quantity, let it be large or small. Nevertheless, after you have gone as far as you can conceive, even to the size of one atom of one of the two elements in the water, if such a paradoxical idea pleases you, the atom is divisible into oxygen and hydrogen. You may follow this idea as far as you please, you make only this, that infinite divisibility is beyond our understanding, and, when we speak and think of it, we have always something finite in our minds. You divide even water, which you know to be compound, to any extent you please, mechanically, and then you have a chemical division beyond it. The division of a sea of water and an ultimate particle is one in science, and Dalton says, Whatever amount of water you choose to imagine, I say it has a definite quantity of O and H. Why is it so? The simplest reason I can find is this, definite bulks unite to form the compound; if the bulks were not definite, then mixtures of elements would occur of various kinds, and we might have an infinite number of compounds of H and O. The fact of definite compounds being constantly formed is a pre-

sumption of a definite size existing for the ultimate particles. But do you mean to say that an atom of salt may be supposed to lie at the bottom of a sea of water, supposing only one atom to be there? I mean, at least, to say that, if an infinitely small quantity of salt were put into a sea of water, it could not be dispersed equally over the sea without bringing in new and still more incomprehensible relations between one part and another. When a small quantity of oxygen fills a large space, we are obliged to suppose motion in the particles, an attempt to be in several places at once, and without this theory we have more difficulty. It suits our understanding, and the nature of the things we see, to say at once that an atom of salt may be supposed to lie at the bottom or top of a large quantity of water.

But, says an opponent, I look on the elements themselves as mere centres of forces, and, if so, there can be no atom.

Dalton might say: "They may be centres of forces for all I know, but that does not take away from them materiality; it is merely another mode of expressing matter."

Opponent: "Not exactly, because if there is only force, then it may be infinitely divisible, or, at least, it can be conceived so more readily."

Dalton: "I do not see this. If a piece of iron is proved to be a force, it is not the less a piece of iron. If an ultimate particle of water be proved to be two forces or more, it is not the less a particle of water, and divisible into H and O, which you may call gases or forces as you please."

Opponent: "But, if they are forces, then it may be that, when we find O and H uniting, it is an act of many unseen powers very complicated, none of them being elements, but making elements by combining."

Dalton: "That is the same supposition virtually as before, but remember it is a supposition, and I came to deliver you from many such fancies. If it be true, then I may assure you that these forces come in very definite quantities, and act as much by quantity as my supposed atoms do, and if they become solids they must be treated as such. Indeed my idea of obtaining definite compounds by bulks or ultimate parts has expanded itself into the idea of equivalents, a very useful word invented by that most ingenious chemist Wollaston, and my pupil Joule has extended it to force—its rational development. To me it matters not whether force be the original of matter or not, or whether force and matter be the same or not; surely I am quite well acquainted with such variations. Although I call Wollaston ingenious, I do not admire his word equivalent. It arises from a suspicion and unfamiliarity with the idea, or, as I would say, from ignorance."

Opponent: "But, then, if there is force only, and not bulk, to begin with, how do you get the combination to be definite?"

Dalton may say again: "I found it difficult, and therefore I kept to matter, which, however, may simply be the expression of force. I take it, however, in the shape given to me by nature. No one has ever shown me an oxygen-producing force in action. Still let us examine the proposition. If oxygen should occasionally split up into X and Y, forming two elements, it may be that all our other elements may do the same, or something similar; we might then have many more elements, or fewer, perhaps only one at last. That I think possible enough. We should then have a chemistry beneath our chemistry, a new era like that

brought in by Davy when he began the chemistry of the earthy and alkaline oxides. That newer chemistry may come, but it must apparently be caused by a new power, because we have tried to decompose our elements by the forces we have, and they will not yield. If one prefers to speculate on such a chemistry, let him do so; but do not suppose that any such result will alter the present theory as applied to present natural conditions."

It is clear that no one has yet explained how the smallest quantity of water, and the largest, should have a definite composition, except Dalton; and many men have tried it. If one O and two H's unite to form every conceivable portion of water, nature has given us no reason to suppose that these parts can be indefinite. The first conceivable portion of water being composed of two parts is not infinitely small. If you say that, both being infinitely small, two must be so also, I must demur; two nothings do not make a something, but two infinitely small bodies must, even to our imaginings, make something more definite. At the same time, however, I must remind you that we cannot understand the meaning of "infinitely small," and when we struggle we make in our minds a definite size. The same thing applies to "infinitely divisible." At the same time, this is not conclusive, only illustrative, and the best arguments lie in the fitness of the Daltonian atoms to make definite compounds. I object to have an intelligible theory put aside by an unintelligible, even on the supposition that perhaps it may some day be intelligible. Notwithstanding difficulties, men will rush at infinitely divisible matter, and form definite compounds out of it. By what means do they obtain the first idea of definite size? Dalton shows how he begins it. Let us learn another way of beginning it. How does volume come out of no volume? How does equivalent come out of shapelessness? It is as easy to throw clay into the fire unshapen, and to bring out bricks; it is as easy to decide how something came from nothing. We are compelled to seek a beginning for ourselves to rest on, uncertain whether a real beginning, to which we cannot attain, preceded that which we seem to comprehend. If you will go farther, and break up our chemical and intelligible atom into a theoretical one; you begin a new science; but you must feel uncertain whether you will ever be able to experiment with these new elements of the sub-Daltonian atoms, or Daltonian substratum of matter without atoms; or whether we have passed out of the region of that more occult chemistry in cooling down, or whether we are moving towards it, and, in the condition of mercury, shall attain it.

At any rate, I trust that in discussion chemists will remember to distinguish between the Daltonian atom of our chemistry and that of the mind bewildered with the incomprehensible idea of infinity. I do not enter on other proofs of atoms from the laws of gases, &c., &c.; I wish only to attempt to make an arrangement in discussing the Daltonian chemistry, and advise chemists to be careful in throwing aside opinions until they have better reasons than any given. The President of the British Association did good service by bringing forward the subject as I think.

Such ideas I have often spoken of, and you will not require me, I hope, to sign my name, as I have no time for discussion at present, and I can escape it better by writing simply as an

ATOM.

DIDYMIUM IN SCHEELITE.

By CHARLES HORNER.

SCHEELITE from some localities, I find, contains didymium, notably the specimens from Traverella, Piedmont,—plates of 2 m.m. thickness showing the characteristic group of lines at D to great advantage. Although the lines are very distinct, yet the amount of this element must be exceedingly small, since a borax bead saturated with the finely-powdered mineral failed, in a vitreous condition, to show even a trace when examined by the spectroscopic. However, after allowing the bead to cool, and then gently re-heating it according to the plan adopted by Mr. Sorby, the didymium crystallised out, showing the spectrum to perfection.

I have observed didymium in Cumberland scheelite, but it appears to be absent from some American specimens.

ESTIMATION OF CARBON IN PIG-IRON.

By GEORGE S. PACKER.

THE following method for the estimation of carbon in pig-iron, and having reference to a paper by Mr. C. H. Piesse (CHEMICAL NEWS, vol. xxviii., p. 198) on the same subject, may be of interest to some of your numerous readers:—

2.5 grms. of pig are treated with 50 to 60 c.c. of CuSO_4 (1:5), and, after standing 7 to 8 minutes in the cold, the solution is gently warmed, until the pig is completely decomposed; there is then added 20 to 25 c.c. of CuCl_2 (1:2) and 50 c.c. of (pure) strong HCl , and the solution is gradually brought to boiling; by this time the precipitated copper should be re-dissolved (time, 45 to 50 minutes); it is then filtered through an asbestos filter, made as follows:—

The usual asbestos funnel—a tube about 8" long and 1" diameter, drawn out at one end to a neck about $\frac{1}{2}$ " diameter—has some pieces of very thin glass rod, about $\frac{1}{4}$ " long, placed side by side firmly in the narrow end, and above these some previously ignited asbestos, loosely plugged, about $\frac{1}{4}$ " thick layer; some hot water is then run down the funnel to consolidate the asbestos, and the solution is then filtered and washed in the usual way.

This filtration and washing can be done in 5 to 7 minutes, unless the pig be very siliceous, when it sometimes takes 20 to 30 minutes; if the solution be allowed to boil for some time, or even stand (over-night, for instance), the Si forms gelatinous SiO_2 , which greatly hinders filtration. The asbestos and carbon are now placed in a 200-c.c. flask with 3 grms. C_2O_3 , using as little water as possible for rinsing in; the flask is fitted with a 2-oz. stopcock funnel and delivery-tube to conduct the gas first through a U-tube containing some H_2SO_4 only (I find a wash-bottle and H_2SO_4 allows the acid to run back if a draught should blow the light under the flask a little on one side for an instant), and then through one containing broken glass and H_2SO_4 , and then into potash-bulbs. The funnel is filled with strong H_2SO_4 (40 c.c.), and, when the connections are all made, the acid is allowed to flow slowly in; the solution is gradually brought to boiling, and kept so a minute or two, till all evolution of gas ceases; air is then drawn through the apparatus, allowing it first to pass through potash solution to absorb atmospheric CO_2 , and the bulbs weighed. Time, $1\frac{1}{2}$ to $1\frac{3}{4}$ hours.

This method is a modification of that of A. H. Elliott, given in the last edition of "Fresenius" (by A. Vacher). I have described it rather fully for the sake of any who may not have easy access to the above-named edition.

My intention in writing this has been to call attention to the method, which gives very concordant results, and can be executed with great rapidity. I have repeatedly done a determination, including all the necessary weighings, in $2\frac{1}{2}$ to $2\frac{3}{4}$ hours. In the case of steels, or in pigs where the drillings cannot be obtained so fine, of course the

solution in CuSO_4 takes longer; and in steels, where a larger quantity must be taken for analysis, the reagents must, of course, be proportionately increased.

COMMUNICATION FROM THE LABORATORY OF CHARING CROSS HOSPITAL.

By T. BOLAS.

On the Estimation of Oxidised Nitrogen in Potable Waters by means of the Ferrous Sulphate Test.

IN testing for nitric acid as already described (CHEMICAL NEWS, vol. xxviii., p. 249) it is quite possible to float the aqueous liquor on the vitriolic fluid with such steadiness as to cause the surface of the latter to assume the form of a sharply-defined meniscus. In this case it is necessary to give a slight rotatory motion to the vessel containing the test in order to produce the small amount of heat which is required for the production of the dark compound. The formation of a meniscus should always be aimed at, as a much greater intensity of colour is attained when the meniscus is produced, and subsequently destroyed by careful rotation, than when the aqueous liquid is added in such a way as to cause a sensible amount of agitation. When the "nitric acid test" is employed, the dark tint appears in the vitriolic stratum, and not, as when the ordinary method is used, in the aqueous stratum; and, moreover, if the rotation be continued, the upper portion of the vitriolic stratum remains coloured to the last, even if the aqueous liquid has become hot enough to instantly decompose the dark compound.

Under any circumstances, the quantitative indications obtained in this way are, as previously pointed out, somewhat vague. This arises, to some extent, from the difficulty of producing equal temperatures in both tubes. The delicacy of the test, when performed as now recommended, is fully equal to that attained in the usual way, 1 part of oxidised nitrogen in 25,000 being recognisable in either case. When, however, the operation of testing is conducted in such a manner as to produce the dark tint throughout the whole mass of the liquid, the delicacy of the reaction is increased four-hundred-fold, and 1 part of oxidised nitrogen in 10,000,000 parts of water becomes capable of recognition; and, moreover, the tints thus produced are well adapted for the colorimetric determination of small quantities of oxidised nitrogen.

The colorimetric comparison is best made by mixing the water to be examined with its own volume of pure sulphuric acid; and, after cooling, 80 to 85 c.c. of the mixture are placed in a tall jar, 15 to 20 c.c. of the nitric acid test being then added, and under these circumstances the heat produced is sufficient for the formation of the compound $2(\text{FeSO}_4) \cdot \text{N}_2\text{O}_2$, but it is not sufficient to destroy this compound. These proportions are suitable when the temperature of the materials is 14° to 17°C. , and a rise of about 10° takes place on mixing. Having thus produced the brown tint in the test, a mixture of vitriol with an equal volume of a standard solution of nitre is similarly treated, and the tints of test and standard are compared. If the standard is rather darker than the test, a portion of the former may be removed in order to make the intensity of colour equal in both jars, and, of course, the portion removed must be considered in calculating the results. Similarly, a portion of the test may be removed if its tint is slightly darker than that of the standard.

When waters containing a large proportion of nitrates are being examined, it is advisable to use smaller jars than those required for 100 c.c. of liquid, and it is scarcely necessary to remark that evaporation must be resorted to when the proportion of nitro en is smaller than 1 in 10,000,000. If the water contain organic matter which blackens under the influence of vitriol, or if it is naturally dark in colour, it must be distilled, with the addition of

about one-fourth of its volume of sulphuric acid, and the distillate, which should be equal in amount to the water taken, must be treated as described above.

In preparing the nitric acid test, it is better to use pure oil of vitriol than the commercial article, as in this case the application of heat is not required. Although a solution of ferrous sulphate containing far less of the salt than the amount required for saturation may be used in the preparation of the nitric acid test, it is advantageous to prepare it according to the directions already given, and to allow the deposited crystalline salt to remain at the bottom of the stock-bottle, the separating salt acting to some extent as a decolorant.

In order to avoid an undue consumption of vitriol in making comparisons, I intend to try how far discs of glass, either coloured, or covered with a coloured varnish, may be substituted for the standard solutions,

ON HEAT.*

By FREDERICK GUTHRIE, B.A., F.R.S., &c.

THE "Sources of Heat" and "Expansion" were treated of as follows:—

In considering what we may call the laws of any physical force, we are necessarily led some time or other to study the way in which the force affects ourselves. In fact, the only inlet is through our various organs; but in all, or most cases, it is necessary, before studying this, to get some notion of the objective relations of the phenomena themselves. The eye is generally the organ which is selected for final accurate measurements. Although we may appreciate sound through the ear, yet we may feel the body throb with our hands even. We may distinguish between pitch by the ear, but for accurate measurements we refer to the eye. Measuring wavelength is a thing chiefly of vision, partly of touch, but not of hearing, taste, or smell. So, in considering heat, we shall soon find ourselves compelled to come to the eye. With regard to the sensation of heat, of course you usually understand that it can never furnish an accurate measure of temperature. The sensation of heat appeals to the same nerves as the sensation of touch, but the body itself has a certain temperature, and what you really feel as the sensation of temperature derived from touch is not a direct appreciation of temperature at all. But it is an appreciation of loss or gain of heat in those liquids surrounding the nerves of touch, and whereas for the other forces, such as sight and sound, taste and smell, bundles of nerves are employed, almost all parts of the body are sensitive to heat. The different nerves are differently sensitive to heat as to touch; but the same nerves which take up the sensation of touch take up the sensation of change of temperature—the loss and gain of heat being what we appreciate by plunging our hands into hot or cold water. This gives rise to the terms hot and cold. My hand loses heat in cold water, and I have the sensation of cold, whereas another person, whose hand is warmer, may feel hot.

So, at starting, we are obliged to abandon the cutaneous sensation of hot or cold as a measure of temperature. It is simply a measurement of our own sensitiveness and the temperature of the blood at the time. We must therefore return to certain physical effects which will be referred to the eye as the measuring organ. Perhaps the most conspicuous physical effect is that of expansion, or the property which heat has of increasing the lengths of bodies.

Roughly speaking, we may lay down the rule that all bodies expand by heat; that is, if we take a cubic inch of matter, on heating it becomes a cubic inch and

* Abstract of the first of a course of Lectures to Working Men, delivered in the South Kensington Museum on Monday, the 17th ult.

something more, expanding in all directions. If we take a linear yard of matter, that yard expands the same fraction of its thickness in all directions as it does of its length. In this way, by taking a thin and long rod or wire of matter, I may exaggerate expansion and render it palpable.

A platinum wire is made red-hot by passing a current of electricity through it. One end of the wire is rigidly fixed to an upright rod, while it is kept stretched by a weight at the other end. This weight is in communication with an index, which shows the lengthening of the wire on heating and its constriction on cooling. The same effect may be shown by a copper sphere which passes through a cold ring of brass; but the ball, heated for a few seconds, expands, and refuse to pass through until it cools to the temperature it was before, or rather till the ring and the sphere reassume the same temperature, both higher than to begin with.

One may also appeal to the sense of hearing, in order to prove the expansion of solids by heat. A rocker of copper is placed upon a bar of lead and heated, but no action ensues. If the rocker be tipped on one side, however, it causes a little mountain of lead to be formed, which tilts over the copper just as in shrugging the shoulders. This takes place so rapidly—more than sixteen times in a second—that one hears the successive blows of the copper on the lead. They produce a musical note, just as all rapidly succeeding sounds do.

All these experiments have been to show the expansion of solids, sometimes appealing to the eye, sometimes to the sense of hearing. Now let us see that liquids expand when they get hot; after that we will take the third form of matter—gaseous, and show that gases expand also.

Let us take, as three typical liquids, water, alcohol, and mercury. Surround these with hot water; and, as solids expand by heat, the first effect of this hot water will be to heat the glass and increase its capacity, just as the hole of the ring increased. The level of the water sinks because the same quantity has to fill a greater capacity; but the glass does not expand so much as the water, hence the expansion of the water prevails over the expansion of the glass, and the level of the water rises. Alcohol and mercury behave in a similar manner.

In the same way, let us take an example of the most familiar gas of all, or a mixture of gases—atmospheric air. That air expands when heated is illustrated by many toys, the balloon depending on the fact that heated air is lighter than cold. We have, say, a cubic yard of air; expand that, and it still has the same weight when expanded as it had when cold; but take a cubic yard of that expanded air, and the weight is evidently less.

Coming from toys to scientific instruments, we have here a means by which atmospheric temperature can be measured. The differential thermometer, so-called because it shows when the one bulb is heated more than the other, and not that one place is warmer than another, is composed of two bulbs connected by a glass tube twice bent at right angles. The air expanded by heat forces a liquid or an index towards the other bulb, and thus variation in temperature is communicated.

Having seen that solids, liquids, and gases expand by heat, let us pursue the subject further, and see the expansion which *different* solids undergo by heat.

If I surround a brass rod with ice-cold water, then with boiling water, marking the expansion, afterwards expose a similar rod of iron to the same conditions, there would be a difference of expansion between the two metals. The expansion of different metals are measured roughly in this way.

That solids expand differently for the same temperature may be shown by a bar of iron rivetted to a bar of brass. The bar of iron below receives the heat first, and expands, and the bar bulges out towards the iron; but iron does not expand so much as brass for the same increase of temperature; hence, when the heat has penetrated through the iron to the brass, the brass assumes the form of the arch

to gratify the relative expansion of the two metals. Another means of showing the same effect is by a compound ribbon of platinum and silver in a spiral form. On the application of heat the spiral unwinds, because of the expansion of the inner coil of silver, and on cooling it is reversed. Attached to an index on a dial, this is used as an atmospheric thermometer. We have established the point that solids expand unequally for the same increase of temperature, and this inequality also prevails with liquids.

We will experiment with three equally filled flasks of water, alcohol, and mercury, all heated to the same temperature. The difference in expansion is seen in the different level of the various liquids.

In the case of gases, no such inequality of expansion exists, as different gases expand to the same fraction of their volume when heated through the same range of temperature.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 275).

LECTURE VI.

The Energy of Light, especially with reference to the Measurement and Utilisation of it.

THE energy of light is all-pervading. Wherever life is, there this energy is. Darkness, or absence of light, is another name for death. That our knowledge of the mode in which this energy acts is "cabined, cribbed, confined," there can be no doubt. It has, however, an extended influence; indeed, there is reason to infer that it has an actual active kinetic power which may be described as enormous, even when separated from its usual allies, heat and actinism. The very small area of explored light-land only serves to assure us by its embarrassment of rich energies that in respect to light there are not only as great, but even greater developments to be made, than have yet taken place in any of the "imponderables."

The animal, vegetable, and mineral kingdoms; solid, liquid, and gaseous matter, each, in some form or other, admits of the energetic action of what passes under the general name of light. Such universal consent to the power of light, which recent science investigations seem now, for the first time in the history of the human race, to be making known, is rendering a spontaneous but somewhat unconscious and undesigned testimony to the truths of Scripture. In the first chapter of the book of Genesis, and at the third verse, we read that the very first act of creation is light—"Let there be light." It must be admitted as singular, very singular indeed, that that old book—the Bible—about which some men cavil, should have had written in it of events occurring, say, 6000 years ago (six million years ago, if you please), that which science-investigation of the last 50 or 100 years has only made clear to all who read. Strange that this, "offspring of Heaven first born," without which no life can even now be sustained in healthy vigour, should have been formed in the fulness of energy before revelation asserts that life was. The strangeness ceases when the religious faith in inspiration enters.

Before this lecture is closed the conclusions and illustrations, if successful, will prove that, whilst this energy is less comprehended, and, if possible, more perplexingly mysterious than even the energy of affinity, it is nevertheless one whose presence is for vigorous action. Even the conducting power of bodies for electricity have within the last few months been shown to be so connected as to be influenced by light.

It is not in my power to produce the experiment, but it may be stated that if a small bar of selenium—say two inches long, and one-eighth of an inch diameter—have

* The Cantor Lectures, delivered before the Society of Arts.

its ends electrically connected with such a galvanometer as you saw last week, then the speck moves as light shines upon or is excluded from the bar.

The sources of this energy are the sun, the stars, and meteors which, in some way unknown to us, setting aside the theory of luminous heat consequent upon atmospheric friction, are self-luminous.

There is no similar self-luminosity on earth. If it be wished to obtain light from other and accessible sources it is done by extraneous agencies. Heat caused either by affinity, electricity, or mechanical means, or by a concentration of the energies of some self-luminous source, is the way by which we usually produce light.

This process of production by concentration from self-luminous sources, although generally adopted, is very unpromising as a means for ascertaining the energies of such source-produced light. For this reason—as the light passes through or is reflected from the bodies employed in the concentrating operation, the extent or degree in which this energy may have been expended in chemical or physical work within or upon the concentrating body cannot be ascertained. Hence the remaining work—be it represented chemically or mechanically—is all that is left for investigation. It represents but the balance of the account. Now, as a coin so small as one shilling may represent the balance of two accounts, neither of which reaches one pound, so the same coin may represent a balance of accounts reaching many thousand pounds. Clearly, then, from this remaining work no inference can be drawn respecting the total of the energies involved in the production of such a balance.

The energy of light varies with the source from which it originates. In some respects, viz., as regards heat and light, properly so called, the energetic elements in what we call the electric light are more similar to those in the sun than any from other lights within our means of artificial production; in another respect, viz., chemism, or actinism, the energy of that from the combustion of magnesium is nearer to solar light than is the electric.

There are two lights which seem to have in themselves no traces of an energy producing effects on any of our appliances. They are the result of some unknown and as yet unappreciated energy. These are lights due to phosphorescence and fluorescence.

The decay of what was once possessed of the energy of vitality is a condition manifesting phosphorescence, a state in which light is without much (if any) heat. Whether the light on being given out is the result of some new operation of what was once called the vital principle, or whether it is a consequence of some elements of affinity approximating in character to those we call combustion, is an unsolved problem. Friction, also the passage from a formless state to the state of crystal, frequently causes a phosphorescent light to be emitted.

Phosphorescence is a name also given to a mode of obtaining light which seems to depend upon the property that certain bodies possess of rapidly concentrating within themselves the light they may receive from being exposed in the neighbourhood of a luminous body, and then emitting this absorbed light gradually. Probably the light stored up in a few seconds is not emitted in less than minutes.

Diamonds and other substance shine in the dark for a short time, after exposure to intense light. This shining of certain crystals, in the absence of light, probably led to the opinion that such crystals were living beings, petrified by light in the hands of men. Certain flowers, especially those with bright yellow petals, sometimes emit a sudden flashing light a little after sunset; also, some plants growing in mines emit light from their whole surface. Certain preparations continue to emit this light so intensely and continuously as to be used as night-lights—not for illuminating rooms, but for such purposes as reading the hands of a watch.

There are in this box a series of tubes which, doubtless, appear to all of you, at the present time, perfectly

white. If, however, we allow an intense light to shine upon them, they are seen to possess a phosphorescence that will last some time—from ten minutes to half-an-hour, as the case may be. This magnesium lamp shall be lighted, and the tubes exposed to its rays for a short time, and you will see, not only the simple phosphorescence, but different colours which the contents of each tube assume.

Fluorescence is a peculiar appearance consequent upon placing some substances in certain position with respect to light. This may be illustrated by the action of light upon sulphate of quinine. In this bottle is what appears as pure colourless water; it is a very weak solution of sulphate of quinine. If looked at in the presence of light rich in actinic rays, a change in the appearance is observed. A piece of magnesium ribbon is now lighted. In certain angular positions a beautiful azure blue may be noticed; this blue is a consequence of those phenomena called fluorescent. These, phosphorescence and fluorescence, are two characteristics of the energy of light, of which all we know is that we can render no account of the causes of them, unless the theoretical explanation be accepted that the two may be classed as one—by regarding them as consequences of an alteration in certain wave lengths in portions of the entire beam of light. From the previous statements it may be inferred that the measurements of the energies of light are not yet accomplished; also, that two lights, which to the eyes do not differ much in intensity, or in what some might call power, yet may show very different energies. It must be borne in mind that here, as in electricity, intensity is not energy; there may be great intensity and little energy.

The great source of light is the sun, and whatever may be the speculations of science, either as to the cause of that light, or as to the mode in which it is propagated from the sun and received at the earth, they do not concern us at present. What we are concerned with is, how are the energies of the light thus received, and of such artificial lights as are utilised, to be measured?

A reference to the diagram of the spectrum may explain what is manifested by an analysis of solar light. Observe, there is shown in this spectrum heat, light, and actinism, or chemism, as it is sometimes called. The spectrum visible to us is the part thereon coloured, containing the usual prismatic colours, red, orange, yellow, green, blue, indigo, and violet; therefore the light, properly so called, and which is utilised by human eyes for vision, extends from the letter A to the letter H, and no further, and any energy consequent upon the state which occurs before the letter A, and any energy consequent upon the state beyond the letter H, is not the energy of light properly so called. Now, to our left of the letter A, extending over a space which bears a proportion to light, about half as long again as light, is a space containing the energy due to heat. To our right, beyond the letter H, extending to a distance longer than that of light, we have a space in which photographers and chemists delight. Chemists can get nothing out of this dark end to our left except heat, and chemists and photographers get nothing out of that dark end to our right except chemical action. The intensity of heat lies here, just before we reach light at all; and the intensity of chemical action lies there, just after we get beyond the light. No scientific investigation has yet detached the energy of light and its intensity from these two energies with which it is associated. At this line, marked D on the diagram, it will be noticed that those curves, indicating heat and actinism, die out. The one seems to be passing into the other. At D is what mathematicians might name a "cusp"—a zero on the scale similar to that zero in the arithmetical tables which may be said to mark the turn between counting by integers to the left, and by decimals to the right. At D is this dead blank for heat and actinism, and yet it is there the energy of light really lies. Before the end of the lecture something more

should be said about the energy of light at this particular point. Amongst these three constituents of a solar beam—heat, light, and actinism—there are several marked and extraordinary differences, yet we call them all "light." For instance, heat causes bodies to expand, but heat fails to make an impression upon the retina. Professor Tyndall, some years ago, put his eye into the focus of a heat beam where platinum was melted, and it produced no impression upon the eye. In his account of the experiment he says he did it, but he does not advise anybody else to do it—a piece of advice likely to be more generally accepted than advice usually is. This shows that heat fails to make an impression upon the retina. Heat also fails to produce any photographic result; heat can be conducted along metals, and heat can cause organic and inorganic bodies to expand.

Light, properly so called, possesses these qualities. It makes an impression upon the retina, it effects changes in organic bodies, and probably (in some way mysterious to us) in inorganic bodies also. Light does not possess these qualities—it cannot be conducted by metals, it cannot cause bodies to expand. Now, as to actinism, or chemism, it possesses these qualities—it produces photographic results and chemical changes in organic as well as in inorganic bodies. It does not possess these qualities—it fails in making an impression on the retina, it cannot be conducted by metals, and it cannot cause bodies to expand. Hence there seem to be properties in each portion of the spectrum which do not exist in the other; therefore in the comprehensive term—light—there are three distinct elements, and it is really an error to write them under the one name light. Great would be the social misunderstandings if, because wheat, barley, and oats are all called corn, or grasses, these general terms were as constantly applied to them as the term light is to phenomena with which it is associated, but not connected.

There is also another form in which the energy of light is presented, *i.e.*, in its penetrative power.

For lamps and lighthouses this penetrative power is all important. Certain substances in combustion are possessed of this power in a much higher degree than other substances. It is not, however, only in the material burnt, but further in the mode of burning, that this penetrative power is manifested. The same substances under different conditions manifest very different energies in the emission of light to a distance.

Even the ordinary paraffin lamps—how very inferior in illuminating power some are to others. The utilisation of the energy in the one and only way in which it can be utilised without waste is well illustrated in the various constructions for the burning of different hydrocarbons, to which time forbids further reference. Many present are aware of the different schemes now before the public for obtaining both light and heat from the combustion of the hydrocarbons.

But it is not in liquids only that this difference exists. Even the same quantities of gas—*i.e.*, of a suitable gas—one containing such an element as carbon under different circumstances, yields lights of marvellously different penetrative power.

Here is a common gas-burner; if a short tube having a few holes at the bottom be placed over it and the gas lighted at the top of the tube, you have a light which has a certain non-penetrating power. It cannot penetrate far; it has a pale blue lambent flame. Now if the tube be taken off, and the gas lighted at the burner, you have the same quantity of material burning, but with a very different penetrating power. In this case it is evident that the penetrating power depends entirely on the mode in which the apparatus is arranged for combustion of the gas.

From the remarks made it may be inferred that science is yet incompetent to pronounce decidedly, 1st, what or which element or elements in the solar beam constitute light properly so called; 2nd, even if this be deter-

mined positively, yet science is still undecided by what rule, or weight, or measure, the energy of light is to be gauged.

Indeed this remark may not be an exaggeration—in all probability no two persons see the same degree of light. It may be surmised that no two persons see any portion of this spectrum of the same colour, and, further, it is highly probable that there is no such thing as colour in nature at all. It is likely that colour is a pure impression produced upon the retina of each person's eye by the vibrations of the medium which strike upon it. Hence what we call red, orange, yellow, green, blue, indigo, and violet do not exist actually on the spectrum, but in the eye of the observer, and probably one person will see the red beginning here, and extending thus far, whilst others will see it beginning a little more to the left, and ending a little more to the right, or *vice versa*. Upon that point there is nothing really settled.

As to the first of the foregoing inferences the energy of light is said to be concentrated in the yellow portion of the visible spectrum. If the views of those whose pursuits are photographic are to be received, the perplexities of science are increased. The very name of their art—photography—indicates the writing of or by light alone.

The fact is that photography is not a process dependent upon light as light, but upon that portion of light which is possessed of certain peculiar and hitherto unexplainable influences of a chemical character. Photographic chemistry is as yet very partially understood—were it not that those who think they understand it might be offended, the truth would not be outraged by saying that photographic chemistry is not at all understood. And yet no process for estimating the energy of light, as light, has been suggested more hopeful for success than that dependent upon chemical changes; but these are not those chemical ones to which the photographer appeals. The fact is, that those changes appreciated by the photographer can be produced in inorganic compounds; what they are can be partially noted, they can be recorded, and that in terms which are but relative (not absolute), and which chemistry alone can measure. The day may not be distant when the energy of light, as light, will be duly and absolutely measured.

Judging from its place in the order of creation—previously named—judging from its influence over the whole world of animal and vegetable existences—judging from such facts as that when light is absent all animal and vegetable life lapses into a species of torpor, or sleep, and on the return of light nature awakes, and resumes its activity and strength, the conclusion is a very legitimate one, that in light—as light—there is great energy. Light opens the eyes, not of animals only, but even of flowers; hence one of our little English flowers is called "The day's eye." Those who can sleep through noise, and even through heat, are not insensible to the energy of even artificial sources of light playing, however gently, upon the closed eyelid. Medical men and nurses are well aware how essential light is for the regaining of health and strength by the sick or the infirm. Egypt and Madeira, as sanatoria or convalescent homes for our ailing brothers and sisters, may owe more of their influence to qualities or energies of light very different from those the photographer esteems than are usually allotted to them. And it may be permitted to add that marvellous testimony to some unknown element (be it figurative or be it real) which, whilst pervading all Scripture from Genesis to Revelations, assumes a most marked peculiarity in that expression of St. Paul (Eph. v., 14), "Awake thou that sleepest, and arise from the dead, and Christ shall give thee [marvellous gift] light" not life, observe, but—"light."

(To be continued.)

* This subject has been examined more in detail in "The Harmony of the Bible with Experimental Physical Science," published by Bell and Daldy, price 2s. 6d.

CORRESPONDENCE.

ALUM IN BREAD.

To the Editor of the Chemical News.

SIR,—“Og” in his letter (CHEMICAL NEWS, vol. xxviii., p. 262) asks for an explanation of the “Shoreditch case.” The commentators have so unceremoniously adopted the misleading statements made at the Shoreditch meeting of master bakers, excepting in the case of the *Times*, that one can only deplore their readiness to arrive at anything sensational by any means, and learn that truth is not always sought after. You intimate your intention of publishing an article on the subject; prior to your so doing, allow me to request you will read the enclosed copy of a letter sent to my Directors, who asked me for the full particulars of the case. It is curious to observe how, in hurried exercise of judgment, even technical journalists are capable of publishing most gross mistakes. One of these (*Iron*), in commenting on adulterations, observes that a chemist in seeking for sulphuric acid pursued a course that would effectually destroy it, alluding, I have no doubt, to a published statement of mine that “the bread was burnt in a platinum vessel, and the ash carefully examined for alumina, &c.” This reporter or editor, in his wisdom, conceived, I suppose, that the sulphuric acid must be decomposed and lost, whereas the ash when oxidised should have yielded satisfactory evidence both of the presence of alumina and sulphuric acid, unless ammoniacal alum had been employed; even then the water-solution or extract should have given evidence of H_2SO_4 . In the Shoreditch case, the test failed to detect the constituents of alum (in any appreciable quantity) said to be introduced as an adulterant, and the question put to me was to determine whether it was “bad bread adulterated with alum,” which charge it was certainly free from.

There has been so much misrepresentation that I gladly take this opportunity of placing the facts before you, that you may know what actually occurred and what course was pursued.—I am, &c.,

E. V. GARDNER, F.A.S., M.S.A.,
Professor of Chemistry.

Royal Polytechnic Institution,
Nov. 25, 1873.

IRON FILINGS IN TEA.

To the Editor of the Chemical News.

SIR,—Mr. Alfred H. Allen (CHEMICAL NEWS, vol. xxviii., p. 275) says that he has found “genuine iron filings” and “real lumps of iron in tea.” As the subject is of considerable practical interest, and Mr. Allen’s testimony is of unquestionable value, I venture to ask him two questions—(1) Were these found in the ash or in the unburnt tea? and (2) How did he determine that the particles of iron were genuine filings, and what was the quantity of these and the lumps?

As regards the supply of iron filings, Mr. Allen says that he has no doubt that he could beg a hundredweight of finely divided iron to-morrow. My Sheffield experience, to which Mr. Allen refers, satisfies me that he is quite right, but would it be so easy to “beg” such refuse if it were systematically used for the adulteration of tea,—if there existed a market for anything like the quantity that I have shown would be required? It is just because they are not used for any such purpose that the various kinds of iron dust produced in Sheffield are so worthless. If there were a demand for the large quantity (5,000,000 lbs. per annum) that would be required for the alleged adulteration, all the iron-works of the world would, as I have already stated, be attacked by collectors of the material, and Sheffield—being capable of producing more than any other place in the world, probably more than could be produced throughout the whole of the Chinese Empire—would be thus attacked the most vigorously, and Sheffield

iron dust would be worth as much as Sheffield armour-plates, and quite as difficult to “beg.” If this adulteration were carried on at home, as Mr. Allen supposes, both he and I would have seen or heard of truck-loads of iron dust being loaded up on the sidings of the Sheffield railways and forwarded to London, which is the wholesale tea-mart of Britain.

While differing with Mr. Allen on this subject of iron filings, I take this opportunity of expressing my admiration of the manner in which he, Mr. Wanklyn, and Mr. Bird have studied the subject. The working of the Adulteration Act has strikingly displayed one of the most important influences of scientific education. The exceptional few of competent chemists who have had the courage to accept the post of public analyst have distinguished themselves by the modesty of their certificates; they have fairly measured the difficulties to which Mr. Allen has referred; and we might almost affirm that the amount of adulteration detected by the different public analysts has varied inversely with the amount of their chemical knowledge and analytical skill. The best chemists have, doubtless, best understood that their office demands a special technical skill, for which the education and experience obtainable in our ordinary chemical laboratories only affords the preliminary, though necessary, scientific basis, and that further and special preparation is necessary in order to qualify even the ablest of our chemists to fulfil satisfactorily the duties demanded by the Adulteration Act.

This is well illustrated by your article in last week’s number of the CHEMICAL NEWS, on “Alum in Bread.” Such difficulties as are there explained, and the conflicting evidence obtained in every prosecution where the shop-keeper has been able to afford the cost of obtaining further analyses than those of the public analyst, have proved the cruelty and injustice of the hasty and ruinous convictions that were based upon the half-crown analyses and superficial certificates in the early prosecutions under the new Act of Parliament, and enforce the necessity of the utmost caution in the meantime, until practical and special experience has enabled the public analyst to master the difficulties of his newly-created business.—I am, &c.,

W. MATTIEU WILLIAMS.

PS.—Since the above was written, I have read the able summary of the Birmingham tea cases by Mr. Kinnersley, the Stipendiary Magistrate of Birmingham. It is fully reported in the *Grocer* of Nov. 29, and I recommend it to the perusal of your readers interested in this subject. It appears from this that further experiments have induced Dr. Hassall to reconsider his former conclusions; he has just written to state that he now concludes “that the iron detected in the tea was not really iron filings, but magnetic oxide and crushed ore.” This is a strong confirmation of my theory of the origin of the iron that has been detected in tea.

PUBLIC ANALYSTS.

To the Editor of the Chemical News.

SIR,—Will you kindly allow me space for a few remarks on the subject which called for your leader in the CHEMICAL NEWS of last week? I thoroughly agree with the remarks you then made, and I only think that they did not go far enough. The subject of the competence of the public analysts appointed under the Adulteration Act is a very important one, both from a social and from a scientific point of view; and I think I may safely say that the growing distrust of the public as to the value of the act itself, and particularly as to its administration, is more than proportionally shared by members of the chemical profession generally, and who are not personally interested in carrying out the Act, but who look on from outside as impartial critics.

The adulteration question seems to oscillate, in the public regard, between two “poles,” if I may use the

simile—the “positive” one of panic, and the “negative” one of indifference—both extremes being mischievous, but that one of panic being by far the most hurtful. Adulteration panics are often aided greatly in their development and progress by persons who, being ignorant of the subject on which they write, are therefore the more enthusiastic, or else by others who have some interest to serve by raising an agitation on the subject.

Much of the mischief arises from two very common abuses—viz., the appointment of incompetent men to the office of analyst, and to the plurality of appointments held by the same analyst. This latter often necessitates the employment of assistants, sometimes engaged at a low rate of remuneration, the only part of the duties performed by the public analyst himself (besides drawing his salary regularly) being the signing the certificates, and the assuming the responsibility of defending them if called in question in a court of law.

I, as a chemist, am glad to observe that most of the *fascos* hitherto made public have been the work of medical officers of health, and not of regular professional chemists. When will people be disabused of the idea that, because a man may make a successful diagnosis of a medical case, he is, *ipso facto*, equally competent to perform a complex chemical analysis? These frequently occurring “mistakes” are calculated to lower the prestige of the analystship, not only in the estimation of the public, but, what is of much greater consequence, in that of the better part of the chemical profession. It is to be feared that all this will end in deterring competent chemists from accepting the office of public analyst, and will leave the vacancies to be filled by young and incompetent members of the profession, or by medical gentlemen, who, as a rule (with certainly a few bright exceptions), are generally unfitted, through want of proper training, to fill the office.

In the interest of society at large, and of the chemical profession itself, it is very desirable that the whole subject should be thoroughly discussed in its various aspects: and, in my opinion, there is no more suitable medium for doing so than the columns of your valuable journal, which, occupying as it does, the first position in English chemical periodical literature, is presumably read by all persons who may be supposed to be interested in this subject.

Seeing how small is the amount of information on “food analysis,” of any real practical value, at present available, there can be no doubt that a series of essays on the subject, appearing in the *CHEMICAL NEWS*, and written either by yourself or by some other competent authority, would be of very great value at the present time, and they would be highly appreciated by very many of your readers, myself among the number.—I am, &c.,

WILLIAM RATCLIFFE.

Wolverhampton, Dec. 2, 1873.

[Such a series of essays is in preparation, and will shortly commence.—Ed. C. N.]

ON THE COEFFICIENT OF EXPANSION OF CARBON DISULPHIDE.

To the Editor of the Chemical News.

SIR,—In your report of the meeting of the Chemical Society last week, you represent Professor Foster as saying that there must be an error in my calculations. I am sorry to say that he is perfectly correct; I have inadvertently introduced an error into the formula for calculating the expansion. I make this avowal to prevent any scientific man from being misled by the figures given in your report, but the corrected numbers will be given when the paper is published in the Society's *Journal*. The only excuse I can offer is that I was attempting to do too much, and, when persons have too much business and brain-work all day, they generally find their heads are never so clear at night for calculations.—I am, &c.,

J. B. HANNAY.

Dec 2 1873.

EVOLUTION AS APPLIED TO THE CHEMICAL ELEMENTS.

To the Editor of the Chemical News.

SIR,—In the issue of *Nature* for Nov. 6, Mr. Blanshard has drawn attention to the above subject by a letter, in which he pre-supposes that this theory has not been discussed before.

Allow me to refer him to a letter by the writer, published in your journal (vol. xxiv., p. 131), in which a parallel was drawn between the derivation of the endless variety of plants and animals from one or more simple forms, and the integration of all the so-called chemical elements and compounds from one primordial matter.

Again (vol. xxvi., p. 138), a paper was published by me, on the “Constitution of Matter,” in which I sketched some of the considerations leading to the conclusion that from one primordial matter have been developed or evolved all those integrant parts the study of which constitutes the science of chemistry. To substantiate such views it is chiefly necessary to prove the identity of the matter of one element with that of all other elements, and this can best be done, perhaps, by showing that those properties, considered as peculiar to each element respectively, are properties which are determined by a definite expense of force in each case.

I do not wish to engage in any discussion on the matter, but perhaps I may be excused for pointing out that the above views seem to be gaining credit. Thus, at the meeting of the Chemical Society on May 15 last, Dr. Armstrong pointed out that “isomerism” admits of an easy explanation, if it be assumed “that different amounts of force have been expended in the formation of the isomeric compounds,” and, as Dr. Mills then stated, it was eight years since he had propounded and published a dynamical theory in explanation of “isomerism”—a theory “parallel to that proposed by Dr. Armstrong. The connection between such views and the evolution of the elements is at once evident.—I am, &c.,

CHAS. T. KINGZETT.

Kensington, W., Nov. 25, 1873.

PHOSPHORUS A TEST FOR IODATES.

To the Editor of the Chemical News.

SIR,—I observe in your “Chemical Notices from Foreign Sources” of Nov. 21 a notice of phosphorus as a reagent for iodates. Without wishing in any way to detract from the author's merit as being the first to publish this reaction, I may yet be permitted to state that I became acquainted with it more than eighteen months ago, while experimenting on the presence of iodate of calcium in sea-water. I made many experiments on the action of phosphorus on the iodates, one of which I find mentioned in my note-book, under date May 3, 1872, and as this particular experiment, referring to the action of *red* phosphorus, has still a shade of novelty, I give it:—“Red phosphorus diffused in water acts, especially when heated, upon iodate of calcium, liberating iodine. The phosphorus, added in excess, with addition of hydrochloric acid, gives a clear colourless liquid.” I enclose the leaf, torn from my note-book, containing this account. I used carbonic disulphide, containing a minute proportion of phosphorus dissolved in it, as a confirmatory test for the presence of an iodate in sea-water. But the experiment requires great care in order to get a satisfactory result; for, if the phosphorus is in excess, the carbonic disulphide (containing phosphorus in solution), when shaken up with sea-water, becomes opaque and of a brownish or violet tint, owing to the reduction of some traces of metals from sea-water, which, being collected by the disulphide, give that appearance. With proper care it is, however, possible to get the veritable iodine reaction from sea-water by this test; but the danger of the confounding of the true and the simulated reaction by some who might repeat my experiments without sufficient care,

deterred me from publishing the fact, especially as I gave adequate evidence of the presence of iodate in sea-water without it. Moreover, I intended to make further investigations as to the metals in sea-water which give the reaction referred to, and I have not yet been able to complete these. Hence the delay in publishing the observation I made as to the action of phosphorus on iodates.—I am, &c.,

E. SONSTADT.

Ramsay, Isle of Man, Nov. 24, 1873.

HYDROGEN AND SOLUTION OF NITRATE OF SILVER.

To the Editor of the Chemical News.

SIR,—Dr. Williamson's assertion that the solubility of hydrogen in water diminishes with rise of temperature, will probably surprise those of your readers who happen to have read Bunsen's admirable text-book on gas-analysis.

According to Bunsen, the solubility of hydrogen in water is the same for a wide range of temperature (the coefficient of solubility being 0.019.) According to Bunsen hydrogen is distinguished from most other well-known gases by the constancy of this coefficient.

Whether Dr. Williamson's remark touching the solubility of hydrogen was made at random, or whether it was a record of unpublished experiments of his own, I am unable to determine. Dr. Williamson's statement that hydrogen is more soluble in solution of nitrate of silver than in water; and his suggestion that some chemist should make a measurement of the solubility of hydrogen in nitrate of silver, during the interval between the commencement of the passage of gas through the liquid and the first appearance of precipitation, calls for comment. It will be evident that, on the assumption that the first action of hydrogen is to reduce nitrate to nitrite of silver, the resulting nitrite cannot make its appearance until sufficient nitrite has been formed to saturate the solution. The experimenter who overlooks this fact will be in danger of calculating the hydrogen which has combined with oxygen as if it were existing in solution in the nitrate of silver.

For my own part I am inclined to doubt whether solution of nitrate of silver dissolves more hydrogen than water does; and I should advise caution on the part of any young chemist who is disposed to follow Dr. Williamson in this matter.

J. ALFRED WANKLYN.

Dec. 1, 1873.

MISCELLANEOUS.

The Royal Society.—At the annual meeting of the Royal Society, held at Burlington House on December 1, the following gentlemen were appointed officers and council for the ensuing year:—*President*—Joseph Dalton Hooker, C.B., M.D., D.C.L., LL.D. *Treasurer*—William Spottiswoode, M.A., LL.D. *Secretaries*—Prof. George Gabriel Stokes, M.A., D.C.L., LL.D.; Prof. Thomas Henry Huxley, LL.D. *Foreign Secretary*—Prof. Alexander William Williamson, Ph.D. *Other Members of the Council*—Sir George Biddell Airy, K.C.B., M.A.; Sir B. C. Brodie, Bart., M.A., D.C.L.; Professor Arthur Cayley, LL.D.; John Evans, Sec. G.S., F.S.A.; Daniel Hanbury, Treas. L.S.; Nevil Story Maskelyne, M.A.; Prof. James Clerk Maxwell, M.A.; C. Watkins Merrifield, P.R.S.N.A.; Joseph Prestwich, V.P.G.S.; Andrew Crombie Ramsay, LL.D.; Rear-Admiral G. H. Richards, C.B.; Prof. George Rolleston, M.D., M.A.; J. S. Burdon Sanderson, M.D.; William Sharpey, M.D., LL.D.; Francis Sibson, M.D.; Major-General R. Strachey, R.E., C.S.I. After the anniversary dinner, the Fellows of the Society adjourned to their new apartments at Burlington House.

Public Analyst.—Professor Alfred Anderson, Public Analyst to the Vestry of St. Martin-in-the-Fields, and Professor of Practical Chemistry in Queen's College, Birmingham, has been appointed Public Analyst to the Board of Works for the Poplar District.

Physical Society.—A preliminary meeting was held on Saturday last, in the Physical Laboratory of the Science Schools, South Kensington, to consider the formation of a Physical Society. The chair was taken by Dr. J. H. Gladstone, F.R.S. Thirty-six gentlemen were present, including most of the Physicists of London. It was resolved that the following gentlemen be requested to serve as an organising Committee:—W. G. Adams, E. Atkinson, W. Crookes, A. Dupré, G. C. Foster, J. H. Gladstone, T. M. Goodeve, F. Guthrie, O. Henrici, B. Loewy, Dr. Mills, A. W. Reinold, and H. Sprengel. A letter was read from the Lords of the Committee of Council on Education, granting the use of the Physical Laboratory and Apparatus at the Science Schools, South Kensington, for the purposes of the Society.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in utilising alkali waste in the manufacture or production of building materials. J. Buchanan, manufacturing chemist, Hebburn, Durham. March 1, 1873.—No. 752. The invention consists in combining the waste with sand, gravel, rock, slag, waste glass, ashes, or other similar materials. The combination is effected by grinding the materials together, and the compound is moulded into bricks or blocks or used as a cement.

Improvements in the manufacture of soda and potassa. James Hargreaves, chemist, Widnes, Lancaster, and T. Robinson, iron-founder, of the same place. March 3, 1873.—No. 764. This consists in heating a mixture of sulphate of soda or potassa with carbonaceous matter and metallic oxide or oxides to a point short of fusion. The mass is then cooled without exposure to the atmosphere and lixiviated.

An improvement in dyeing and fixing of what are known as aniline colours. Edward Hunt, professional chemist, Worsley Street, Salford, Lancashire. March 3, 1873.—No. 766. This Provisional Specification describes dyeing and fixing aniline colours upon cotton and linen yarns and fabrics with a mordant composed of an aluminous salt combined with gelatin and tannin.

Improvements in treating catechus, cutch, or gambier, to obtain products therefrom suitable for use in tanning, dyeing, and printing. Edward Hunt, professional chemist, and George Manley Hopwood, both of Worsley Street, Salford, Lancashire. March 4, 1873.—No. 783. This provisional specification describes treating the catechus, cutch, or gambier so as to separate the material so treated into two products, the one suitable to the requirements of the tanner, and the other to the requirements of the dyer and printer.

Improved processes for the extraction of iodine. Bristow Hunt, Serle Street, Lincoln's Inn, Middlesex. (A communication from Alvaro Francisco Carlos Reynoso, Paris.) March 5, 1873.—No. 799. This invention comprises the following processes:—(A.) Three processes for the extraction of the iodine contained in iodates, applicable to the extraction of the iodine contained in the mother waters, of the treatment of "caliche" in the mother waters, of the purification of American nitrates, and other similar products. (B.) Two processes for the extraction of the iodine contained in the form of iodide.

NOTES AND QUERIES.

Sulphide of Sodium in Black-Ash.—Would any reader please say what is the readiest method for estimating the above for manufacturing purposes where many samples are examined daily?—A SUBSCRIBER.

Vanadium in Iron Ores.—Can anyone inform me of a reliable method of estimating quantitatively the amount of vanadium in iron ores or pig-iron?—S. P.

TO CORRESPONDENTS.

ERRATUM.—In CHEMICAL NEWS, vol. xxviii., p. 277, col. 1, for "G. Bulk Francis," read "George Bult Francis."

Notes on Natural Philosophy.

By G. F. RODWELL, F.R.A.S., Science Master in Marlborough College, late Lecturer on Natural Philosophy in Guy's Hospital.

"There cannot be a doubt that this little book will be of use."—*Nature*.

"A well-arranged and carefully-written condensation of the leading facts and principles of the chief elements of Natural Philosophy."—*Chemical News*.

J. & A. CHURCHILL, NEW BURLINGTON STREET.

SUPPLEMENT TO THE CHEMICAL NEWS.

Vol. XXVIII. No. 732.

THE EXAMINATION OF BLOOD-STAINS.

A COMMISSION, composed of MM. Mialhe, Mayet, Lefort, and Cornil, have furnished an interesting report on this subject (*Repertoire de Pharmacie*, July 10th, 1873; *Progrès Medical*, August 23). They point out that in the present day it is no longer possible, in the examination of blood-stains in legal medicine, to rest satisfied with the physical characters observed by the naked eye. The microscope, sometimes alone, but more often associated with chemical analysis and the spectroscope, enables us to obtain an exact diagnosis formerly impossible in a great number of cases. Two conditions may occur.

1. When the stain is of recent date, or supposed to be so, the red corpuscles should be particularly examined, and every care taken to preserve them without change. The stains must not be washed with water, so that the hæmatin may not be altered. After insisting on the microscopic characters of the blood-stains, isolated or compared with those of various animals, the commission enumerate with care the fluids which are destructive or preservative of blood-corpuscles. Among the first, water, and particularly hot water, acetic, gallic, hydrochloric, and sulphuric acids; and of alkalies, potash and soda, even in weak solution, and ether and chloroform, and many other reagents, so alter the blood-corpuscles as to cause them to entirely disappear. Alcohol, chromic and picric acids, and bichromate of potash, preserve the corpuscles, though they alter their form. The preservative fluids are those whose composition approach nearest to serum, such as the iodised serum of Schultze, an excellent preparation, made with amniotic fluid, to which are added a few drops of the tincture of iodine, so as to give it the colour of white wine; or better, a fluid composed thus—white of egg, 30 grammes; distilled water, 270 grammes; and chloride of sodium, 40 grammes; or even a fluid containing 0.5 per cent of chloride of sodium, or 5 or 6 per cent of sulphate of soda. If the stains be wetted and softened by these fluids and then examined, white and red corpuscles and fibroid particles will be observed.

2. In more difficult cases, when the microscope, owing to the alterations which time has effected in the hæmatin, can give but vague information, examination by the spectroscope and chemical analysis enable us to arrive at precise results. The use of these means, being less known and also more delicate, requires special study.

1. *Spectrum Analysis*.—Colouring matters have the power of absorbing certain coloured rays of white light—the same always for the same substance. This is the principle on which spectroscopic examination is based. If into an analysing tube filled with water a few drops of a solution of hæmoglobin be introduced till it has the colour of peach-blossoms, the luminous rays of the spectrum passing through this fluid present two bands of absorption between the lines D and E of Fraunhofer in the yellow and the green. The same fact would be observed if a few drops of blood were substituted for hæmoglobin in the analysis. In a case of doubt, the hæmoglobin of the blood could be reduced by adding to this latter a reducing body. Destroyed hæmoglobin has a different spectrum from oxygenated hæmoglobin; a single absorption-band as large as the two former bands united, and a little to the left of Fraunhofer's line D.

2. In blood in a state of decomposition, or which has

been treated by acids or caustic alkalies, hæmoglobin is changed into a new substance; hæmatin is formed, which, combined with hydrochloric acid, gives characteristic crystals. In order to obtain them, we must proceed thus. A small fragment of dried blood is placed on a glass slide; it is dissolved in a drop of water, and a minute portion of sea-salt is added. It is covered with a thin slide, and pure acetic acid is made to pass between the two slides, and it is heated over a spirit-lamp to boiling-point. Acetic acid is again added, and it is heated afresh, and this is repeated till the crystals are obtained. They are rhomboidal, of a dirty brown colour, quite characteristic, and require to be seen with a magnifying power of three hundred or four hundred diameters. With the smallest quantity of blood these two reactions can always be produced—the spectrum examination and the crystals of hydrochlorate of hæmatin; and they are so certain, that the existence of one alone enables one to affirm the presence of blood.

3. The third process, though not so exact as the preceding, ought nevertheless not to be neglected. If to a very small quantity of blood dissolved in a little water be added a few drops of tincture of guaiacum and of binoxide of hydrogen, a persistent blue colour is immediately produced; but this very sensitive reaction can be obtained with other organic matter, nasal mucus, saliva, &c.; it therefore only gives a probability. We must proceed in the following manner. A tincture of guaiacum is prepared with alcohol at 83 degrees, and guaiacum resin; a mixture of sulphuric ether and binoxide of hydrogen is also made, and enclosed in a stoppered bottle, and kept under water in the dark. This preparation is less liable to change than pure oxygenated water. The object stained with blood, if it be white, is put into a little cup, then moistened with water to dissolve out the blood-stain, and washed in distilled water; this water is then submitted to the action of these reagents. If the stain be coloured, and the stain little or not at all visible, it must be moistened and then pressed between two or three sheets of white blotting-paper, and tried first with the guaiacum. If the stain be of blood, a reddish or brown spot will form on the paper. One of the sheets should be treated with ammonia, and the stain will become crimson or green. A second sheet, treated with tincture of guaiacum and ozonised ether, will give a blue colour more or less intense, according to the quantity of the blood.

To recapitulate: 1. If the stains or scales of blood appear recent, the corpuscles may, after the necessary precautions, be examined under the microscope, and their presence, diameter, &c., observed, which will enable one to diagnose the origin of the blood, whether human or animal. 2. If the stains be old and the blood changed, the reaction with the tincture of guaiacum would make the presence of blood probable; but its actual presence cannot be affirmed without spectrum examination, or the production of crystals of hydrochlorate of hæmatin: one of the two is sufficient. It is unnecessary to add that these reactions do not show whether the blood is human or animal.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, December 1st, 1873.

GEORGE BUSK, F.R.S., Treasurer and Vice-President, in the Chair.

THE following Letter to the Family of the late President was unanimously adopted by the Members present:—

"The Members of the Royal Institution beg to be permitted to express to the family of their late President, Sir Henry Holland, their deepest sympathy in the great loss they have recently sustained. It is a loss in which the Institution largely shares; and it has to deplore a President esteemed by all for his distinguished scientific and literary attainments, for the abilities and varied experience he brought to the performance of his duties; and beloved for the uniform kindness and consideration with which he discharged them. In the published record of his life Sir Henry Holland has acknowledged that his connection with the Royal Institution had been very valuable to him. It is now for the Members of the Institution to testify their profound sense of the exceeding advantages conferred by that association upon the Royal Institution. In it, as he himself has related, he stood by the cradle of some of the most wonderful discoveries of the age, and watched their progress to maturity and fame. He was one of the earliest to witness the production of the alkaline metals by Davy, and among the first to see the small luminous spark elicited from the magnet by Faraday. In later times he was foremost in establishing the Royal Institution Research Fund, and was unceasingly generous in his own large personal contributions to it. As President he was always at his post, ever prompt with assistance and counsel; a sound adviser and a courteous friend. The recollection of his presence in the Institution will not soon be forgotten, and will long remain to be cherished by its Members with affection and regard. The close of such a career must be noted with no ordinary feelings of interest and regret, and the Members of the Royal Institution desire to assure the family of their lamented President how fully they enter into the universal sorrow for his death."

Mrs. Walter Fawcett, and Mr. Charles Craddock Underwood were elected Members of the Royal Institution.

The Duke of Northumberland, D.C.L., was unanimously elected President of the Royal Institution, in the room of the late Sir Henry Holland.

The following lecture arrangements for the ensuing season were announced:—

Christmas Lectures (adapted to a Juvenile Auditory).

Professor Tyndall, D.C.L., LL.D., F.R.S. Six lectures on "The Motion and Sensation of Sound," on Dec. 27 (Saturday), Dec. 30, 1873; Jan. 1, 3, 6, 8, 1874. Before Easter, 1874.—Professor Rutherford, M.D., F.R.S.E. Eleven lectures "On the Nervous System," on Tuesdays, Jan. 13 to March 24. Professor P. M. Duncan, F.R.S. Seven lectures "On Palæontology, with reference to Extinct Animals and the Physical Geography of their Time," on Thursdays, Jan. 15 to Feb. 26. Professor W. C. Williamson, F.R.S. Four lectures "On Cryptogamic Vegetation," on Thursdays, March 5 to 26. Professor G. Croom Robertson, University College, London. Four lectures "On Kant," on Saturdays, Jan. 17, 24, 31, and Feb. 7. R. Bosworth Smith, Esq., M.A. Four lectures "On Mohammed and Mohammedism," on Saturdays, Feb. 14, 21, 28, and March 7. Charles Thomas Newton, Esq., M.A., Keeper of Greek and Roman Antiquities, British Museum. Three lectures "On Ephesus," on Saturdays, March 14, 21, and 28.

The Friday Evening Meetings will commence on January 16, at 8 o'clock p.m. The Discourse will begin at 9 o'clock.

Friday Evening Discourses during the Season will probably be given by Professors Tyndall and Sylvester, Sir Julius Benedict, Mr. A. H. Garrod, Dr. Doran, Mr. Vernon Heath, Mr. Francis Galton, Dr. Burdon Sanderson, M. Cornu, Dr. Carpenter, and Professor Ramsay.

Chair of Chemistry Carmichael School of Medicine (Richmond Hospital) Dublin.—C. R. C. Tichborne, Ph.D., F.C.S., M.R.I.A., &c., has been appointed Professor of Chemistry to the above School of Medicine.

NOTICES OF BOOKS.

Les Engrais Perdus dans les Campagnes. (The Manures Wasted in the Country.) Par N. DELAGARDE. Paris: Librairie Centrale d'Agriculture et de Jardinage.

THIS work calls attention, perhaps in a rather more rhetorical style than would be admired in England, to the serious waste of manurial matters taking place in France. This waste is estimated, apparently without exaggeration, at 2 milliards of francs yearly. He considers human excrement to have more than one-and-a-half times the value of sheep's dung, twice that of horse-dung, and three times that of cow-dung. The dejections of an adult person he estimates to have an average yearly value of 28 francs. Poudrette, a form in which night-soil is commonly used in France, he considers to have lost five-sixths of its fertilising properties, a view which we see no reason for disputing if the method of its preparation is fairly considered. It must be noted that the author confines his estimates and recommendations to the rural districts. Of the loss in the towns and of the method of preventing it he does not treat.

Now many persons will be inclined to deny that any waste of manurial matter takes place in the country. They will ask, What can become of the excrements of man and beast if not applied to the land? But, before manures reach the spot where their action is wanted, they are often suffered to lie for a long time fermenting, and allowing their most valuable constituent, ammonia, to "waste its sweetness on the desert air." No less are they injured, in a majority of cases, by the loss of their soluble constituents, such as phosphoric acid, potash, magnesia, &c. It is something quite common, in passing a farm-yard, to notice a dribble of deep brown liquid oozing from the manure heap, and finding its way to the nearest ditch. Hence, after nourishing the weeds along the water-course, it ultimately flows into the same brook and aids in the pollution of our rivers. In like manner, the village cesspools too often will be found draining into the ponds and streams. Thus, though the manure is ultimately carted in due form upon the fields, it is, comparatively, a mere inert residue deprived of its most valuable constituents. The author proposes to arrest such escapes by substituting for the cesspool portable chests, in which the excrement is brought into contact with copras, sulphate of lime, &c., to fix the ammonia. The contents of these chests can then be regularly withdrawn and applied to the soil. The drainings of dunghills, and the urine, a very large proportion of which runs to waste, both in town and country, he proposes should be carefully collected in appropriate pits or tanks. A mixture which he suggests for absorbing both the volatile and the liquid constituents of excrements is composed of 18 double decalitres of dry earth, powdered and sifted; 3 double decalitres of ashes; 2 double decalitres of gypsum; and 1 double decalitre each of slaked lime and of charcoal dust. In a following section he refers to the waste of dead animals, which are often buried entire in pits. The water in which sheep or parcels of wool have been washed, and the liquid resulting from the retting of flax and hemp, have also considerable manurial value, and, as the author points out, are only used accidentally. He shows that the non-edible fungi, which in some parts of the Continent are very abundant, contain in their moist state about 1.5 per cent of nitrogen, and are consequently well worth collecting as manure. He protests, also, against the burning of straw, by which its nitrogen is dissipated and its mineral constituents thrown into a less available condition. What would be his opinion of a new agricultural steam-engine specially arranged to burn straw, and recommended as a great improvement.

This work, although it does not profess to contain anything new to the agricultural chemist, is likely to be very useful. It calls attention, in a plain, unpretending manner, to losses which, though individually trifling, amount in

the course of a year, and over the extent of a whole country, to sums of national importance, and it points out simple methods for their prevention. The lesson is worth attention on both sides of the Channel.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 27, 1873.

Sixth Note on Guano.—M. Chevreul.—The author has found in guano crystals containing three bases—potash, ammonia, and lime combined with oxalic acid. They are soluble in water, and the concentrated solution is not rendered turbid by oxalate of ammonia, even after the lapse of forty hours. If the solution is much diluted with water, and allowed to stand, it loses its transparency and becomes turbid. The opacity is due to the deposition of oxalate of lime. He has also discovered urate of lime in guano. His researches on guano have revealed facts of crystallisation analogous to this, which he communicated to the Academy regarding the salts of dead bodies.

Purification of Hydrogen Gas.—M. Ch. Violette.—The author finds that if hydrogen is prepared from zinc, and purified according to the method of Dumas, it contains no gaseous compounds of carbon. If instead of zinc, iron (whether wrought or cast) be used gaseous hydrocarbons are produced, and accompanying the hydrogen. Whether carbon exists at all as an impurity in zinc is doubtful, if we consider the mode of its extraction.

Sugar Contained in Vine Leaves.—M. A. Petit.—A kilo. of vine leaves yielded 15.8 grms. of cane-sugar, and 17.49 grms. of glucose. A kilo. of peach leaves yielded 33 grms. of cane sugar, and only 12 of glucose.

Reply to a Note of M. Respighi on the Extent of Variations of the Solar Diameter.—P. Secchi.—In opposition to M. Respighi the author finds no difference in results, with the objective prism and with the interposed prism. The small value he obtains for the solar diameter diminishes by five or six seconds the diameter given in the "Nautical Almanack" ($32' 13'' \pm$). This result agrees with that of Encke, who gives $31' 56''$ and with that of M. Mazzola, lately published in Turin, $31' 57''$; the influence of atmospheric oscillation, irradiation, &c., having been eliminated.

Researches on Crystalline Dissociation; Evaluation and Distribution of Work in Saline Solutions. (Continued).—MM. Favre and Valson.—When salts of strong acids are dissolved in sufficient water there is established in the liquor, and between the elements of the salts, an equilibrium such that each of the metalloidal radicals may be supposed associated with one of the metallic radicals, and reciprocally. This appears specially from the observation of phenomena of *thermo-neutrality*, which has been deduced from the existence of thermal modules. Having studied the question as regards variations of volume accompanying the phenomena of solution, the authors find that the densities of saline solutions have relations of a similar nature. There are modules of density as there are thermal modules; and there is a

neutrality with reference to density as with reference to heat. The authors, for convenience sake, designate this *densi-neutrality*.

New Process of Condensation of Liquefiable Matters Held in Suspension in Gas. (Reply to M. Colladon).—MM. Pelouze and Audouin.—The authors state that the novelty in their invention is the reflecting condensation in the dry state, by simple shock of finely-divided liquefiable matters without the intervention of water, or of any liquid solutions, and without cooling surfaces, both of which M. Colladon employs.

Results of Experiments made at Hyères on the Destruction of Phylloxera by Sulphide of Carbon.—M. Bazille.—The entire cost of treating each stock is estimated at not over 50 centimes.

Action of Condenser on Induction Currents.—Lecoq de Boisbaudran.—While physicists generally admit (the author thinks) that the spectral modifications, produced by introduction of a Leyden jar into the induced circuit, are due to variations of the temperature, and not to any particular alteration in the physical nature of the discharge, he yet offers some remarks in support of this view:—1. One may observe the thermal superiority of the condensed spark over the ordinary spark on comparing together the spectra obtained, under different conditions, by means of the same substance. 2. The effects of the condenser being due to increase of temperature, there is gradual passage from the spectra obtained with the aureole of the ordinary spark to those when a powerful Leyden jar is employed. 3. The action of the condenser does not appear the same in different spectra. 4. The different lines of the same spectrum are not always equally affected by the condenser. 5. The lines intensified by the condenser become nebulous and enlarged. 6. The broadening of narrow lines at high temperature is explained by the perturbations undergone by the molecular movements, when the forces applied are considerable. 7. The lines of emission of solid or liquid substances are nebulous. 8. It seems necessary to distinguish two kinds of continuous spectra proceeding from those of the second order, viz., (a) spectra, the lines of which are enlarged by increase of temperature; (b), those, the lines of which owe their enlargement to the little freedom of the molecules. If, as it seems, there is sometimes a gradual transformation of the shaded bands of a spectrum of the first order into the narrow ones of one of the second order, it is in consequence of an increase of temperature. 9. The sparks of different induction coils present spectral differences to the inequality of the temperatures developed.

Liebig's Annalen der Chemie und Pharmacie.
October 4, 1873.

On Bromtoluols and the Behaviour of their Hydrogen Atoms. (Part I.).—H. Hübnér and J. Post.—A lengthy treatise, extending to 66 pages. The authors, who have been assisted in their researches by Retschy, Hässelbarth, Weiss, Terry, and Müller, treat firstly of crystalline para-brom-toluol and its derivatives, such as α -para-brom-sulphi-toluol, α -para-brom-sulphi-nitro-toluol, α -para-brom-sulphi-benzoic acid, β -para-brom-sulphi-toluol, β -para-brom-sulphi-nitro-toluol, β -para-brom-sulphi-benzoic acid, ortho-sulphi-toluol, and toluol-sulph-hydrate. Liquid ortho-brom-toluol is next examined, with its derivatives, ortho-brom-sulphi-toluol, ortho-brom-sulphi-nitro-toluol, ortho-brom-sulphi-benzoic acid, and meta-sulphi-toluol. In succeeding chapters, the authors show the place of the sulphi group in the crystalline brom-toluol, the inability of the isomeric derivatives of brom-toluol to pass into each other by the action of heat, on the position of the constituents in the brom-toluols formed from bromine and toluol, on uniformities in the proportion of crystalline water, on molecular combinations, and on quantivalence.

Determination of Nitrogen.—S. W. Johnson.—This proposal to use sulphate of soda to replace hydrate of soda in soda-lime has been already noticed.

On Atacamite.—E. Ludwig.—Theoretical considerations on the constitution and possible formula of atacamite, with remarks on brochantite.

Nitro-Derivatives of Naphthalin.—F. Beilstein and A. Kuhlberg.—The authors enter upon an examination of mono-nitro-naphthalin, α and β -dinitro-naphthalin, α -amido-nitro-naphthalin, its sulphate, and mono-nitro-naphthalin reproduced from it. They did not succeed in obtaining a β -diamido-naphthalin. They produced trinitro-naphthalin in four modifications, α , β , γ , and δ , and lastly α and β -tetra-nitro-naphthalin.

Action of Sulpho-Carbonyl-Chloride upon Amides. B. Rathke and P. Schäfer.—It is well known that sulpho-carbonyl-chloride has the property of converting aniline and the amides of the alcohol-radicals into mustard-oils. The authors attempted to prepare two new classes of these oils by means of amido-benzoic acid and benzamide. From the former they obtained a mustard-oil benzoic acid, $\text{CSNC}_6\text{H}_4\text{CO}_2\text{H}$, but with benzamide they were unsuccessful in their attempt to form a benzoic oil of mustard.

On Dibenzamide.—P. Schäfer.—In the experiments referred to in the last-mentioned paper, the author obtained a dibenzamide crystallising with two equivalents of water, $\text{NH}(\text{C}_7\text{H}_5\text{O})_2 + 2\text{H}_2\text{O}$.

On a Polyacetone.—W. Heintz.—The substance in question has the same composition as acetone, but its higher boiling-point proves that its molecule is larger than that of acetone. The author takes it to be the analogue of the duplo-sulph-acetone of Wislicenus.

Preparation of Alanin by Means of Cyanide of Potassium, and on Lactyl Urea obtained as a By-Product.—W. Heintz.—Strecker, to obtain alanin, mixes two parts of aldehyd-ammonia with one of hydrocyanic acid, both in the state of aqueous solution, adds to the mixture hydrochloric acid in excess, and evaporates in the water-bath. Heintz proposes to use cyanide of potassium in place of hydrocyanic acid. He also examines the reactions and combinations of lactyl urea.

Constitution of Natural Silicates.—Dr. K. Haushofer.—A purely hypothetical paper.

On the Polydenes, and on the Transformation of Ethylen into Ethyl-Alcohol.—W. Goriainow and A. Butlerow.—The authors set out with the object of polymerising ethylen. In this they were not successful. Alcohol was obtained in quantity by passing ethylen into concentrated sulphuric acid heated to from 100° to 175° , distilling the acid liquid with a plentiful addition of water, and treating the distillate with potash.

Protein Substances. (Second treatise.)—H. Hlasiwetz and J. Habermann.—The authors saw reason to admit a relation between these bodies and the hydrates of carbon. On treating casein with dilute hydrochloric acid and chloride of tin, the authors obtained glutaminic acid, leucin, and tyrosin, asparaginic acid and ammonia. No hydrates of carbon nor derivatives of such bodies appeared, whence the view stated at the outset of the paper cannot be maintained.

Compounds Belonging to the Camphor Group.—J. Kachler.—The author examines pimelic acid and its ammonium, calcium, barium, magnesium, copper, and silver salts, pimelic ethyl-ether, anhydrous pimelic acid, chloride of pimelic acid, sulpho-camphylic acid, its lead salt, and its behaviour with nitric acid, and concludes with hypothetical speculations on the constitution of certain members of the camphor group.

Isomeric Amylens obtained from the Amylic Alcohol of Fermentation.—F. Flavitzky.—A preliminary notice. The author mentions the following peculiar reaction: if ethylamylic ether is treated with

anhydrous phosphoric acid, and the product condensed in a well cooled receiver, a liquid is obtained, which boils at 35° , and which is probably amylen.

Synthesis of Anthracen and of Dimethyl Anthracen.—W. A. van Dorp.—Benzyl-toluol, prepared according to Zincke's directions, and having a constant boiling-point of from 275° to 277° , was passed through an ignited tube filled with pumice stone, and became converted into anthracen, which when pressed and re-crystallised from glacial acetic acid is pure. It melts at 213° , and contains—

Carbon	94.38
Hydrogen	5.86

100.24

It was capable of conversion into anthracinon and alizarin by the ordinary methods.

On Cœrulignon and its Derivatives.—C. Liebermann.—This paper is unsuited for abstraction; the author gives for cœrulignon the formula $\text{C}_{16}\text{H}_{18}\text{O}_6$, and shows that it is probably a chinon.

On Penta-brom-resorcin and Penta-brom-orcin.—C. Liebermann and Aug. Dittler.—The authors confirm the formula given by Dr. Stenhouse for the former body, $\text{C}_6\text{HBr}_5\text{O}_2$.

Les Mondes, Revue Hebdomadaire des Sciences, par L'Abbé Moigno, Tome xxxii., No. 11, November 13, 1873.

M. E. J. Maumené states that he has discovered two great laws by means of which it becomes possible to calculate the totality of any chemical action whatsoever. He expounds his views at length in a periodical, entitled *Petites Annales de Chimie*. He pronounces the idea of substitution "one of the most fatal ever introduced into science."

No. 12.

This number contains a highly eulogistic notice of the late Dr. Calvert, who was well known in French scientific circles. There is otherwise nothing calculated to interest the chemical reader.

Reimann's Färber Zeitung, No. 42, 1873.

Vat for Woollen Dyeing with Zinc-Powder.—For a vat of 500 litres, dissolve 30 lbs. of soda crystals in water, add 2 lbs. of ground indigo, and 15 lbs. of powdered zinc. The whole is stirred well together, adding 15 lbs. of ammonia (? the strength), and a solution of $1\frac{1}{2}$ lbs. of carbonate of ammonia. The whole is once more well stirred, allowed to settle, and heated to 40° to 50° R. It is immediately ready for dyeing. For every pound of indigo added subsequently there are required $\frac{1}{4}$ lb. of zinc-powder, 2 lbs. of soda, 1 lb. of ammonia, and $\frac{3}{4}$ ozs. of carbonate of ammonia.

The Royal College of Science (Ireland).—We announce with gratification that Professor Galloway has been appointed Dean of the Royal College of Science for the year; and that the Lords of the Committee of Council on Education have decided to amalgamate the Professorships of General and Applied Chemistry in the College, and conferred the joint Professorship upon Mr. Galloway. These changes are the result of the retirement of Sir Robert Kane, the promotion of Dr. Sullivan, and the death of Dr. Barker. The reward bestowed upon Mr. Galloway is only a fair, and too long delayed, recognition of his eminence as a philosophical and practical teacher, and of the zeal and energy he has applied to his duties in the College of Science, and the striking success that has attended the performance of them. The arrangement now made will be for the benefit of the institution, in the prosperity of which the Irish public are so much interested. —*Morning Mail*.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 733.

THE ATOMIC THEORY.

By C. R. A. WRIGHT, D.Sc.

A CORRESPONDENT adopting the signature "Atom" distinguishes, in your columns, between the atomic theories of Leucippus and Dalton, stating that "the first is open to discussion, and will long be, . . . the second . . . is not. We must learn much concerning matter before we can say with certainty that it consists *primarily* of indivisible particles or atoms." He also states that, in writing his paper, he seeks "only to make an arrangement in discussing the Daltonian chemistry."

From the tenor of his note, it would seem that "Atom" does not look upon the views propounded by Dalton, and subsequently extended by others in quite the same light as other writers. Dalton himself ("New System of Chemical Philosophy," Manchester, 1808, p. 213) states that "it is one great object of this book to show the importance and advantage of ascertaining the *relative weights of the ultimate particles both of simple and compound bodies*;" and throughout the work the terms "atom" and "ultimate particle" are used perfectly interchangeably. On page 141 Dalton puts forth his hypothesis thus: "All bodies of sensible magnitude, whether liquid or solid, are constituted of a vast number of extremely small particles, or atoms, of matter."

Later writers have almost uniformly attributed to Dalton the credit of adopting Leucippus's hypothesis, and making it account for the facts (first brought to light by him, *i.e.*, Dalton) of combination in multiple proportion. Gmelin ("Handbook," vol. i., p. 145) states that, "according to the *atomic, corpuscular theory*, matter is an original essence, and consists of certain very small parts, called atoms, molecules, or particles." . . . In the ancient atomic theory "the atoms are supposed to be actuated, not by any attractive force, but by a motion existing from all eternity (Leucippus, Epicurus, Democritus, Lucretius, Lesage);" according to the modern atomic theory (of Dalton and his disciples), "the atoms are supposed to be impressed with innate forces which give rise to the mutual attraction."

The difference between these theories, *quoad* the final indivisibility of matter, is *nil*. On the other hand, a meaning has been latterly attached to the term atom wholly different from that applied to it by Leucippus, Dalton, and modern physicists, *e.g.*, Clerk-Maxwell, Lecture on Molecules to the British Association, Bradford Meeting (*Nature*, Sept. 25, 1873, p. 437). The transition is thus indicated by Dr. Odling (Watts's "Dictionary," article on "Atomic Weights"): "At the present day, the word 'atom' is most generally employed by chemists [in contradistinction to the term 'proportion' used by Davy]; but, while some use it in its strict Daltonian materialistic sense, others use it in an abstract sense, only to express the smallest indivisible combining proportion of a body, and consider the proportional number of a body as an ultimate or unexplained property pertaining to it." From the general tenor of "Atom's" note, it would seem as though he attributed to Dalton the views really propounded by later chemists, and thus expressly stated to be entirely different from the ideas conceived by Dalton himself as to the meaning and application of the term *atom*.

A careful comparison of the writings of modern chemists on this subject leads to the conclusion that many of these chemists admit that the question of the actual existence of the Leucippus-Epicurus-Dalton-Clerk-Maxwellian ultimate particle or atom is in no way raised in chemistry; it may, indeed, be assumed, as when Kekulé accounts for

the identity of 1·2 and 2·3 benzin derivatives by assuming a peculiar kind of vibratory motion amongst the hydrogen and carbon atoms constituting the benzin ring, or when the chemist attempts to account for the fact of combination in multiple proportions. But it is not a necessary condition; on the contrary, numerous arguments tend to show (and not the least, Norman Lockyer's most recent researches) that the hypothesis that sixty-five or more essentially different kinds of atoms exist is not in accordance with the whole range of known facts. To bring this forward somewhat pointedly has been the sole object of the writer's papers on this subject heretofore.

The *atom* now referred to by many chemists is not the same thing as the atom of Leucippus, Dalton, and other physicists; the term connotes wholly different ideas. What is described by these chemists as the "atomic theory" is in fact neither a theory nor is it atomic; *i.e.*, it does not involve the assumption of any proposition incapable of experimental proof (such as the assumption that matter is constituted in a particular way), nor does it refer to the special proposition of the existence of ultimate indivisible particles. It might with more justice be called the *greatest common divisor system*, inasmuch as fundamentally it is a system for co-ordinating chemical facts based upon the ascription to the various elements of numerical values, which are the greatest common divisors of the weights of the various elements obtainable from constant bulks of their gaseous compounds respectively.

The atom of Leucippus and Dalton has no longer a place in this system of chemistry, saving in special cases where it is referred to as a means of explaining the facts collected together in the system. Let the chemists who admit that the question of the actual ultimate indivisibility of matter is not raised in chemistry generally, also agree to use no terms which imply the raising of the question and its mental decision in the affirmative. Let the terms atom, molecule, atomic weight, &c., &c., be replaced by words not involving by implication the assumption, so that these terms may revert to their legitimate use as employed by the physicist; then will the reasoning of such chemists be less unphilosophical and illogical than it often is at present, whilst the student will be spared much mental confusion, and there will be less room for controversy based on misapprehensions as to the meanings attached to the words employed.

A SIMPLE AND CHEAP APPARATUS FOR THE ANALYSIS OF GASES.

By T. BEESLEY, F.C.S.

For some time past I have used a little apparatus for gas analysis, which is so readily constructed from the ordinary materials of the laboratory, is so easy of manipulation, and so satisfactory in its results, that I am induced to bring it to the notice of other chemists.

The apparatus, like that of Regnault, of which it is a modification, consists of two parts:—A laboratory vessel and its trough, in which to receive the gas and submit it to the action of absorbents; and a graduated tube and its adjuncts, in which it is measured and, if necessary, exploded. The laboratory vessel is a cylinder, about 3½ ins. high, and 2 ins. in diameter, holding about 70 c.c. It is drawn out at the top, and a piece of stout thermometer-tube with a fine cylindrical bore, 3 ins. in length, is fused upon it, and bent at a right angle a little above the junction. The measuring-tube is about 20 ins. long, and ¼ in. in internal diameter, and has another similar piece of thermometer-tube attached in the same way to its upper extremity, and bent in the same way. Its lower end is drawn out, so as to allow of a double caoutchouc connector being firmly tied or wired upon it. To the other end of this connector a glass tube, bent twice at right angles, and with the limbs 1½ ins. apart, is fastened in like manner, leaving about ¼ in. between the ends of the two glass tubes. The second

limb passes through a cork firmly thrust into a piece of combustion-tube 4 or 5 ins. longer than the measurer, and projects $\frac{1}{2}$ in. above the cork, the aperture being contracted. The cork carries another bit of right-angle tube, which, with a caoutchouc connector and spring-clamp, forms a mercury-tap. Both tubes are fixed by means of wire and a few slices of cork to the opposite sides of a square mahogany rod mortised into a solid foot. The measurer has platinum wires fused into it just below the top, and is carefully graduated into cubic centimetres and tenths, or has a millimetre scale etched upon it, and is then calibrated. In the latter case, a millimetre scale is also scratched upon the filling- or pressure-tube, to assist in the adjustment of the mercury-level. If the tube is graduated for capacity, a similar scale may be laid down upon paper pasted to the front of the support. The capillary-tube of the measurer has another bit of thermometer-tube, 2 ins. long, joined to it by a good caoutchouc connector, leaving the ends of the

tubes $\frac{1}{2}$ in. apart, so that it may be closed by a spring-clamp. This space may with advantage be occupied by a piece of smaller caoutchouc tube fitting tightly into the larger one. The tube of the laboratory vessel is also provided with a similar connector, which, in use, is slipped over the middle tube, and secured by a few turns of twine. A clamp closes this junction also.

In using the apparatus, an ordinary porcelain mercury-trough is so supported that the capillary-tube of the laboratory vessel standing on its shelf is on a level with that of the measurer. The stand which carries the trough is merely a prism of deal, 3 ins. in section, to the top and bottom of which are fastened pieces of board, 7x6 ins. On the right-hand side of the board serving for table, a slender rod is fastened, upon which slides stiffly, by means of a perforated cork, an elastic wooden clamp, which, grasping the neck of the laboratory jar, supports it firmly, whilst allowing of the needful motion. The flexibility of the connectors allows of the depression of the jar to the bottom of the trough, when necessary. The laboratory vessel is filled by suction in the usual way, and the clamp then closed, leaving a drop or two of mercury in the free part of the connector. The measuring-tube is filled by

pouring mercury into the pressure-tube through a small glass funnel with a contracted aperture. Care must be taken to remove every bubble of air from the two-limbed tube, which may be easily effected by strongly tapping the stand after some mercury has been poured in. When mercury runs from the capillary tube, the clamp is put on, and the end of the tube is thrust into the connector of the jar, and fastened with twine. The gas for analysis is now introduced into the laboratory vessel, mercury is allowed to flow out of the tubes, the clamps are opened, and the gas passes over into the measurer. When the mercury has reached a mark on the horizontal part of the tube of the jar, the clamps are closed, the flow of mercury stopped, and enough of the latter poured in to equalise the pressure. All is now allowed to acquire the temperature of the air, which, as the apparatus has been but little handled, takes but a few minutes, and the level of the mercury then quickly re-adjusted and read off, noticing the temperature by a thermometer hanging from the tube of the measurer. The rest of the process differs so little from that of Regnault, to be found in many manuals, that it is unnecessary to further describe it; it must, however, be recollected that the gas must always be measured under the pressure of the atmosphere. In exploding gases in the measurer, the elasticity of caoutchouc so reduces the violence of the shock that there need be no fear of fracture or derangement of the apparatus. When, however, great contraction is likely to occur, which might draw over the whole of the mercury, followed by air, into the measurer, it is desirable to compress the connector at the bottom of the latter with the clamp or the fingers, so as to get time to pour in the mercury. After explosion, half-an-hour at least should be allowed for cooling. At the time of explosion, as well as during the time of cooling, the capillary-tubes should, of course, be full of mercury. Much would be gained in time, as well as in calculation, and something perhaps in correctness, by enclosing the tubes in a cylinder of water, as in Regnault's apparatus, but this would be at a sacrifice of portability, which is one of its chief merits. Having a convenient underground room of pretty constant temperature, I have as yet not been tempted to try this modification. Experiment has shown that, with proper care, there is no appreciable loss by diffusion through the india-rubber. Hydrogen, after standing for one and two hours, gave almost exactly the calculated contraction when exploded with oxygen. Carbonic acid did not alter in volume in three hours, but when both clamps were open, so as to expose a far greater surface of caoutchouc to the jar, it lost 0.2 c.c. in thirty minutes. Such a case would never occur in the course of an analysis.

As a measure of the capabilities of the apparatus, I give the proportions of oxygen obtained in thirty analyses of air collected under different atmospheric conditions, and from different spots in this town and neighbourhood, and previously deprived of CO_2 , made during the last three months. The highest is 21.09; the lowest is 20.82; the mean is 20.95. The higher numbers are mostly after heavy rains, during high winds, or from air collected on heights at some distance from habitations. They agree with those of Angus Smith ("Air and Rain") in showing that the proportion of oxygen in pure air slightly exceeds that commonly given in books. The eudiometer used was somewhat smaller than that previously described, and was not intended for so delicate an investigation; of course, the CO_2 cannot be determined in such an instrument. The following analysis of coal-gas supplied to this town was made in May last:—

CO_2	=	0.10
O	=	0.29
CO	=	6.33
CH_4	=	42.16
C_2H_2	=	6.23
H	=	43.25
N	=	1.64

100.00

Doubtless, improvements may be made upon this eudiometer; hitherto it has answered all my requirements. Perhaps it might be made of larger size, and yet not be liable to leakage or fracture; the present size requires about 20 lbs. of mercury for eudiometer and trough. In the analysis of coal-gas, &c., where much is done by absorption, I use another similar apparatus without platinum wires, of the same height, but of somewhat greater capacity, for the earlier operations, completing the analysis in the exploding one, which is readily substituted for the former. This obviates the possible spoiling of the exploding instrument by potash, &c., which is troublesome to remove during an analysis.

ON THE ANTISEPTIC AND DISINFECTING POWER OF IODATE OF CALCIUM.

By E. SONSTADT.

In the first of my papers "On the Presence of Iodate of Calcium in Sea-Water,"* I referred to the action of this salt on putrescible matter. Since that paper was published I have continued to make experiments on the properties of iodate of calcium as an antiseptic and disinfecting agent; the experiments have been made with the dry salt, and also with a solution of the salt made by dissolving 1 grm. of the iodate in 1 litre of water. The principal putrescible substances experimented upon have been urine, albumen, fish, meat, and rain-water.

The experiments on urine were begun in the spring of last year. Equal quantities of fresh urine were put into two test-tubes, and to one portion a small pinch of the solid iodate was added: the specimens were placed close together. After a few days the specimen to which nothing had been added became very offensive, and I added to it about a fourth of its volume of the solution containing 1 part of iodate to 1000 parts of water. The next day the offensive odour was gone, but still enough odour remained to make the nature of the fluid recognisable. The specimen to which the solid iodate had been added at no time took any offensive odour, and after several weeks could not even be recognised for what it was by the smell. The minute quantity of solid iodate that had been added to it remained apparently undissolved; up to the present time no sensible odour has been given off by this specimen. I have repeated this experiment several times with like result.

The experiment on albumen was begun on July 30, last year. Two fresh eggs were taken, and the whites put into two similar bottles. $\frac{1}{4}$ decigram. of iodate of calcium was added to, and shaken up with, the white in one of the bottles, the white in the other bottle being left as it came from the egg, for the sake of comparison. The two bottles were kept side by side, sometimes corked, sometimes uncorked, but were always treated exactly alike. The white of egg to which the iodate had been added remained sweet for about six months, after which it began to get discoloured and to smell disagreeably. It is now of a dirty yellow colour, and has a whitish deposit. The other specimen, containing no iodate, smelt disgustingly after about a fortnight, and is at present of a brown colour with brown deposit. The odour is perhaps now equally strong from both specimens, but there is as great difference between the quality of the odours as in the appearance of the specimens.

The experiments on fish have been chiefly made on herrings. Freshly-caught herrings immersed in iodate water (containing 0.1 per cent of iodate) remain in hot weather perfectly good for about four days, after which they begin to slowly change. If dry iodate is sprinkled over the fish (1 or 2 decigrams. of iodate to a dozen fish) instead of immersing them in the solution, the result is

the same, and in neither case is it possible to detect the slightest foreign flavour in the taste of the fish. It is remarkable that the solid, and very sparingly soluble, iodate of calcium, which, so sparsely sprinkled over the fish, can only be in contact with very small spots here and there, should still exercise its preservative power throughout as completely as when a solution is used; that such is the case has, however, been proved, not by one or two experiments, but by many, since both last season and this, I have very frequently eaten fish kept fresh for a few days after being caught, by the dry or wet method indifferently. Salt herrings, a staple article of food in the Isle of Man in the winter time, have more or less of a disagreeable rancid flavour, whether eaten with or without removal of the salt they have taken up. But if salt herrings are first soaked in water long enough to remove as much of the salt as is considered desirable, and then immersed in iodate water for twenty-four hours, they lose entirely this disagreeable flavour, and are completely restored to the condition as to flavour that they were in when freshly caught.

I have made several experiments on the preservation of meat by the iodate, and have obtained results similar to those described for fish. In the case of meat, the solution of the iodate cannot advantageously be used, since the juices are extracted, and the meat thereby injured. A very minute proportion of the solid iodate, sprinkled over meat, will keep it good for three or four days (in summer time) longer than it will otherwise keep, and, if the meat has acquired a taint before the application, the taint is completely removed; this applies to the cooked, as well as to raw, meat. In one case, I sprinkled over a small joint of beef, which, after cooking, proved to be tainted to the bone and in every part, about a decigram. of the iodate. The iodate was simply dropped from between the finger and thumb over—and, of course, only very partially over—the surface of the meat; yet the next day the meat was as good as it was possible for meat to be, and was eaten with much relish. How the nearly insoluble iodate can have produced such an effect over parts that it could not come near to, I do not understand; I only vouch for the fact.

Putrid rain-water becomes odourless and agreeable to drink twenty-four hours after the addition to it of one-fourth its volume of the 0.1 per cent iodate water. A litre of unfiltered rain-water to which 1 centigram. of the iodate (1-100,000th) was added on the 10th of January, and kept in a bottle, is still, to all the senses, as it was on the day the specimen was taken.

Eggs, immersed in the iodate of calcium solution, were after a month not to be distinguished by smell or taste from perfectly fresh eggs; how much longer than a month they may be thus preserved, experience only can determine.

Fresh butter, covered with the iodate solution, loses nothing in quality during three weeks, and would probably have kept good much longer. Butter that has begun to get rancid is greatly improved by soaking for a day or two in the solution, especially if once or twice worked up in it. Salt butter, after the salt has been washed out, and steeped in the solution for a day or two, is, if originally of good quality, made nearly equal to fresh.

Such small quantities of iodate of calcium as may be introduced into food by the treatment described, do not in any way alter the normal taste of the food; the only modification produced is to restore the original flavour when that has been disguised or impaired by commencing decompositions.

In order to ascertain if much larger doses than any that could under any circumstances be introduced into the food eaten at a meal, could produce any injurious effect, I took at various times different doses of the iodate, the largest dose taken being 1 grm. This dose left a slight after-taste in the mouth, but I perceived no inconvenience, except a slight head-ache next day, an increased appetite, and, generally, such effects as might follow taking an ordinary dose of quinine. Some of my friends have tried small doses, such as a decigram. at a time, in some cases with no sensible effect, in others with marked increase of appetite and

increase of vigour. But it is cases of fever and of attack by diseases such as typhus and cholera, propagated by some specific organic poison, that I should expect the exhibition of iodate of calcium to be followed by marked effects. A layman has small opportunity of making experiments in such directions. On one occasion, however, after exposure for some time to foul putrid odours, I found myself attacked by the usual premonitory symptoms of a typhoid fever, and all these symptoms *entirely* disappeared within a few hours after taking about a decigram of the iodate: one of my friends can give similar testimony. It appears to me that the iodate acts simply as a tonic on persons in health, but that, when there is an organic virus in the system, it is a potent agent in destroying such virus and in purifying the system. As a minor application, I may mention that the iodate has given speedy relief in cases of tooth-ache arising from caries.

I have made some experiments on the iodates of sodium, potassium, and of magnesium, in reference to any power they might have as antiseptics or disinfectants, but find them, although not quite without effect, very feeble as compared with iodate of calcium.

ON HEAT.*

By FREDERICK GUTHRIE, B.A., F.R.S., &c.

THIS Lecture was mainly devoted to "Temperature and its Measurement."

The lecturer began by showing that ice is lighter than water—an experiment performed by Nature in the floating of ice on water; further, that water as it freezes swells, and in passing from the liquid to the solid state exerts an enormous pressure. Several vessels are perfectly filled with boiled water, so as to deprive them of air, and screwed up. They are surrounded with a freezing mixture, which converts the water into ice, in which condition it occupies a larger volume, is lighter, and exerts an enormous pressure or bursting force.

In the case of gases, it was shown that they do not exhibit the same difference of expansion as liquids and solids, while all expand when heated equally. To prove this, two equal flasks, containing ordinary air and coal-gas respectively, are equally heated by being placed to the same depth in a trough where hot water is poured in, and there is a certain expansion,—bulk for bulk of each being driven out.

Exactly performed, these experiments give these results:—A cubic foot of hydrogen, or any gas, allowed to expand freely under ordinary atmospheric pressure, from the freezing to the boiling-point of water, becomes one cubic foot and three-tenths and six-hundredths (1.36). It is only with gases more easily condensable by cold than pressure that there is a noteworthy variation from this law.

The nearly equal expansion of glass and platinum enables the one to be fused into the other without any risk of fracture by contraction on cooling. Copper and iron might stick together as long as they were hot, but on cooling both would shrink differently, and separate. This equality of expansion of glass and Pt is used by the chemist to enable him to send an electric spark through gas for analysis, while the inequality of expansion is made use of in the construction of pendulums.

Of course the swing of a pendulum is slower the longer it is, and, since every material of which a pendulum can be formed expands by heat, in hot weather it goes slower, because the pendulum is longer. But by means of two metals, and limiting the size of the one, we can regulate and exactly counterbalance the expansion of the greater length of the other, thus keeping the centre of oscillation constant in position.

The mercurial pendulum is another form. There is a glass vessel containing mercury attached to the rod, and

as the rod increases in length the mercury rises and the centre of oscillation is kept at rest, the pendulum having always the same rate of swing. By the superior expansion of alcohol over mercury, atmospheric temperature may be measured. A little diving-bell of platinum, fastened to a platinum wire, and containing alcohol, is plunged into mercury. When the temperature increases the mercury gets lighter and expands, but so does the alcohol,—the alcohol faster, however, and consequently some of the mercury will be driven out of the diving-bell, and there will be an upward pressure. By making the wire very thin an instrument of extreme delicacy can be made; besides, unlike liquid thermometers, it has the index free, and can register freely in the air.

Next, with regard to the force of expansion, and first of all with a solid. An iron pin is snapped by the contraction or cooling of an iron rod fastened to its centre. We may call this force infinite, considering through what a little degree it moves, and remembering the law of Mechanics—that the less the distance of any motion the greater the force. We are not dealing with a mechanical force, but with a physical force, and the same law holds true, for it exerts that enormous pressure in that expansion and in assuming its original molecular state.

An iron bottle is burst when water freezes in it, because, on freezing, the water swells. Most liquids, however, do not swell, but shrink on freezing, as is shown by the cavity formed in them when they solidify. Numerous and exceedingly curious examples of this molecular strain present themselves, and we may have this force locked up in the molecules for an indefinite length of time. Hot molten glass dropped into water solidifies; the outer crust is cold at first; then the inner molecules get cool, and endeavour to contract, either by leaving a vacuum between themselves and the already congealed solid glass, or by establishing a constant internal strain. There is really no more reason why such a vacuum should be formed in one place rather than the other, and the result is, though difficult to prove, that there is this internal strain, which can be distinguished by disturbing any one part where there is unstable equilibrium. Break off a point, and the whole is converted into powder, showing that the strain has been minutely distributed through the whole mass. Annealing glass is the regulation of the cooling of a semi-solid mass, so that the parts may shrink uniformly.

Liquids, when they expand, also exert an enormous pressure, but not so great as solids, as seen in the bursting of a flask full of water when the water is heated. Take a vessel of water mixed with ice, and heat it, and there will be no such reversal as the glass expanding and the water sinking, as is the case with simple water on heating at first, but the effect of the glass will be in the same direction as the effect of the melting of the ice. When the ice melts it gets denser, the water being more dense than the ice from which it is formed, and this continuous shrinking of the mass while heating proves clearly that, bulk for bulk, ice is lighter than water. Now, amongst all bodies in the liquid and solid form, water stands not exactly alone, but among a select number.

Let us now turn to the means which have been employed for the measurement of temperature, briefly describing the construction of thermometers. A good flask, with a well-fitting cork and a narrow tube, are the elements of a thermometer. But we wish to prevent the evaporation of the liquid, and to get rid of the pressure of the air, and to make the liquid adhere to the sides of the tube. It will be advantageous to take a liquid free from air, and shut the vessel off from the influence of the atmosphere in every way; then it is clear that if we are dealing with a ratio or fraction, and we want to measure the amount water or mercury increased when heated through a certain range of temperature, it is advantageous to take a great discrepancy between the capacity of the bulb and the tube or stem. Practically, it is found best to use a bore tube almost infinitesimally small, for the

* Abstract of the second of a course of Lectures to Working Men, delivered in the South Kensington Museum on Monday, the 24th ult.

smaller the amount of liquid the more readily it assumes the temperature to which it is exposed. One takes a tube far narrower than a hair, and the bulb may be filled with either alcohol or mercury; alcohol, if we are dealing with low temperatures, because alcohol has never been frozen; mercury, if we are dealing with high temperatures, because it requires a high temperature to boil mercury, although it can be frozen.

An ounce of mercury immersed in freezing water always has a certain size, and in boiling water it always has another and greater size, while at any intermediate temperature, got by mixing together freezing and boiling water in different proportions, it has an intermediate size. Accordingly, by measuring the size of any constant weight of mercury, we can tell what its temperature is. Plunge the bulb containing the mercury into freezing water, and the mercury shrinks in the stem to a certain point; plunge it again into boiling water, and it rises to a higher mark. The lower mark is sometimes called 0, and the other 100° (Centigrade) or 80° (Réaumur), or the lower is called 32° and the higher 212° (Fahrenheit).

Let us, in conclusion, notice the important fact that water is at its greatest density at 4° C.; at 3° it stands as high as it did at 5°; and at 2° it stands as high as it did at 6°. A frozen pond bears witness to the fact, for the water at the surface is at zero, while the water at the bottom is at 4° C., i.e., the coldest water rises to the surface, and gravity induces the water at its maximum density (4° C.) to go to the bottom.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 4, 1873.

Dr. FRANKLAND, F.R.S., Vice-President, in the Chair.

THE minutes of the previous meeting were read and confirmed, and Mr. F. Brown was formally admitted a Fellow of the Society, after which the Secretary announced the donations which had been made to the library. The names read for the first time were those of Messrs. Frederick E. Harman, William Herbert Pike, Robert Francis Smith, Henry Bowman, Joseph Reddross, R. L. Taylor, William Joseph Spratling, J. Lawrence Smith, and Owen Davies Owen. For the third time—Dr. B. W. Richardson, F.R.S., Dr. Donato Tommasi, Messrs. Charles L. Field, Walter T. Goolden, B.A., Edgar Beckett Truman, Thomas H. Davies, William Masters, Alexander Campbell Dixon, James Baynes, Thomas Jamieson, Robert Williamson, Charles James Hislop Warden, Francis Jones, Sidney Knowles Muspratt, Felix M. Rimmingtons, Edward Cleminshaw, Samuel Herbert Cox, and Arthur B. Kitchener, who were then balloted for and duly elected.

The first paper, entitled "*Mineralogical Notices*," by Professor STORY-MASKELYNE and Dr. FLIGHT, was read by the former. A specimen which had been sold to the British Museum as aurichalcite, from the Lead Hills, was found, on microscopical examination, to belong to an ortho-symmetrical system, and to possess the same crystallographic form as caledonite. The analyses of the mineral and of an undoubted specimen of caledonite were made, and the results in both cases corresponded to the composition represented by—

indicating a composition corresponding with 3 equivalents of linarite, 2 of lanarkite, and 2 of water. As Brooke states that the mineral contains 9.5 per cent of carbonic anhydride, a determination of the amount present in this specimen was made, and found to be only about 1.4 per cent. The authors think that, as the mineral occurs associated with cerussite, the carbonic anhydride was probably accidentally present in the form of lead carbonate.

An analysis of a very pure specimen of lanarkite showed that it contains neither water nor carbonic acid, but consists of lead sulphate and lead oxide.

THE CHAIRMAN, in thanking Professor Maskelyne and Dr. Flight for their interesting communication on this mineral, said he could not help noticing the remarkable coincidence between the number of molecules of metallic sulphate and those of metallic hydrate, there being five of each.

Professor LAWRENCE SMITH, of the United States, said he had analysed many of the minerals from the mines of Pennsylvania, and he might here mention the ease with which citrate of ammonia dissolved lead sulphate. Anglesite, for instance, dissolved readily in a solution of ammonium citrate, and the lead could then be precipitated as carbonate, and the sulphuric acid subsequently determined.

Mr. FIELD remarked that a solution of hyposulphite of soda answered equally well for dissolving lead sulphate; lead carbonate, on the contrary, was very insoluble.

In reply to an observation of Mr. SPILLER, that he had pointed out in 1857 that lead sulphate was particularly soluble in solutions of the citrates, Dr. SMITH said that he had made assays of lead ores by that method as early as 1852.

Mr. JOHN WILLIAMS then exhibited some fine specimens of phosphates, including the crystallised acid; the latter was prepared by the action of water on pure phosphorus trichloride, the solution being concentrated by evaporation in a platinum basin. On allowing it to stand for twelve or fourteen hours, it solidifies to a crystalline mass; the sodium salt was the only one exhibited which crystallises well. On adding the sodium salt to a solution of platinum, the platinum phosphite is precipitated; this dissolves in the liquid when it is heated, and separates in the crystalline state on cooling. The acid precipitates silver and gold in the metallic state, the latter being coherent and presenting the usual metallic appearance; with sodium phosphate, on the contrary, it is precipitated in a very finely-divided state, and has a purple colour. With silver nitrate, the sodium salt gives the bright yellow silver phosphite, which becomes brown when heated. The crystallised acid itself, when strongly heated in a test-tube, gives off spontaneously-inflammable phosphoretted hydrogen.

Dr. FRANKLAND said the members were much indebted to Mr. Williams for showing them the specimens of the phosphites, which had not received that attention from chemists one might expect. It was a new fact that the acid yielded spontaneously-inflammable phosphoretted hydrogen, it being generally stated that the gas given off under those circumstances was not spontaneously inflammable.

Professor CHURCH then made a communication "*On Autunite*." The published analyses of this mineral usually assigned to it the formula—

Pisani, however, gives it $10\text{H}_2\text{O}$, which is probably correct. The theoretical composition is— U_2O_3 , 60.18 per cent; CaO , 5.9; P_2O_5 , 14.96; $10\text{H}_2\text{O}$, 18.98; whilst $8\text{H}_2\text{O}$ requires only 15.7 per cent. On making an analysis of a specimen of Cornish autunite in beautiful lemon-yellow needles, the speaker found— U_2O_3 , 60.00 per cent; P_2O_5 , 13.84; and H_2O , 18.65; which corresponds to the formula with $10\text{H}_2\text{O}$. In order to obtain additional evidence on this point, crystals of French autunite were carefully selected under the microscope, powdered and dried; over sulphuric acid they lost 8.24 per cent of their weight, and at 100° 6.94 more, in all 15.14. A loss of $8\text{H}_2\text{O}$ would require 15.18. At 180° they lost 3.09, and at low redness 1.03, making 4.12; a loss of $2\text{H}_2\text{O}$ would require 3.79. The speaker said he hoped shortly to be able to complete his results and lay them before the Society in detail.

Professor MASKELYNE observed that there was great difficulty in determining in what state the water existed in a mineral, and when Professor Church gave his complete description of the mineral, he hoped he would state whether

the loss of water over sulphuric acid was accompanied by a breaking up of the crystal. In a very fine specimen of the mineral, which had been about forty years in the British Museum, he had noticed a peculiar abraded or worn appearance of the crystals near the summits, for which he had been quite unable to account.

Professor CHURCH replied that he had observed that the Cornish mineral became somewhat greenish when dried *in vacuo*, but the French, whilst it retained its colour, became opaque. In an account of the corresponding phosphate of uranium and copper, published some years ago, he had noticed that its green colour became changed to yellow on drying.

Professor LAWRENCE SMITH, whilst describing a burner employed by him for heating crucibles, alluded to his process, published some time ago, for separating the alkalis in siliceous minerals, depending on the manner in which lime decomposes the silicates. One part of the pulverised mineral is mixed with 1 part of ammonium chloride, and then 8 parts of calcium carbonate, precipitated by ammonium carbonate from a hot solution of calcium chloride, are added. The mixture is introduced into an elongated platinum crucible, and heated to redness by means of a modification of Bunsen's burner having a sort of mouth-piece adapted to the top of the tube, so as to cause the flame to spread out somewhat like that of a "fish-tail" burner. The fritted mass, after removal from the crucible, is treated with water and ammonium carbonate to precipitate the lime, and the alkalis determined in the usual way; the whole operation on a felspar occupying about two hours and a half.

During the course of the evening a gas-burner, by Mr. F. FLETCHER, of Warrington, was exhibited.

The CHAIRMAN finally adjourned the meeting until Thursday, December 18th, when the following papers will be read:—"Researches on the Action of the Copper-Zinc Couple on Organic Bodies" (No. IV., "On Allyl-Iodide"), by Dr. J. H. Gladstone, F.R.S., and Mr. Alfred Tribe; "On a New Compound of Nickel and Phosphorus," by Dr. R. Schenck; "On the Preparation of Standard Trial Plates to be used in Verifying the Composition of the Coinage," by Mr. W. Chandler Roberts.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 4th, 1873.

R. ANGUS SMITH, Ph.D., F.R.S., &c., Vice-President, in the Chair.

Mr. Joseph R. Bridson, Mr. James Watkins, and the Rev. William Marshall, B.A., were elected Ordinary Members of the Society.

The CHAIRMAN said that the death of Dr. Calvert, one of the most distinguished members of the Society, called for more attention than he was able to give it, but this meeting of the Society could not be allowed to pass over without a few words regarding the loss which all chemists must feel. It will no doubt be the pleasant duty of some of his friends to prepare a more detailed account of his labours. Meantime he (the Chairman) would express the opinion of all who knew Dr. Calvert by saying that a more diligent student of chemistry has rarely, if ever, been found in any country. It has been remarked that Dr. Calvert's knowledge of the literature of science was something marvellous; this was doubtless owing to his devotion to the subject and his untiring activity and strength. The memoirs which he has written are too numerous to be characterised at present, and already several journals have given the heads of the most important. As a medium of communication between scientific men, manufacturing and professional, in France and England, he was no doubt the means of doing much good in both countries. In the former country he felt almost as much at home as in the latter, having lived there from the time he was fourteen

years of age until he was twenty-eight, and having married a French lady. It was this intimate connection with France which gave him his French accent, which he could never entirely get rid of. He was, however, entirely English by birth. His habits contracted there may have led also to that excessive activity which seems to have told at last in a very unexpected manner upon his health, as he seemed powerful and of sound constitution. The fatigues he underwent during a visit to the Vienna Exhibition, and the climate there, must, however, be blamed, so far as we can hear, for the evils both direct and indirect which produced a fatal result. Dr. Calvert had, shortly before his death, completed a revised edition of his lectures on some departments of manufacturing chemistry. His practical experience, combined with his profound knowledge of the theory of the subject, must render such a work of great value, and keep his name for a long time fresh among chemists. His later investigations, especially those connected with germs or the beginnings of life, were of a purely scientific character. He may be said in every sense to have been a successful man until that illness which destroyed a life which promised to be very long. He had many friends, and amidst an excessive amount of work he was able to be obliging and kind to a large number. He was a Fellow of the Royal and Chemical Societies and of several foreign Academies, and in the scientific circles of London and Paris he was as well known as in his adopted city, Manchester, where many lament him as a man who knew little of him as a chemist.

"On the Bursting of Trees and Objects Struck by Lightning," by Professor OSBORNE REYNOLDS, M.A. The results of the experiments referred to in this paper were exhibited to the meeting. The suggestion thrown out by Mr. Baxendell at our last meeting—that the explosive effect of lightning is due to the conversion of moisture into steam—seemed to me to be so very probable that I was induced to try if I could not produce a similar effect experimentally.

(1). I first of all tried to burst a thin slip of wood by discharging a jar through it, taking care so to arrange the wood that the discharge should be of the nature of a spark, and not a continuous discharge. This was done by making the wood to form part of a discharging rod, with balls on the ends.

This experiment was successful in the first attempt, although the results were on a small scale. It should be mentioned that the wood had been damped with water. This experiment was repeated with larger pieces of wood with various results.

(2). It then occurred to me to try with a glass tube. This I did at first with a very small tube, passing wires from the ends of the tube until they were within $\frac{1}{4}$ inch of each other.

The small tubes burst both with and without water.

(3). I then used a larger tube (about $\frac{1}{4}$ inch bore), using it in a similar manner. The discharge without water produced no effect on this, even when repeated several times, but when the tube is full of water (with the ends open) the first discharge shattered that part of the tube opposite the gap in the wire. This tube was bent in the form of a syphon, and the water stood about 1 inch beyond the gap in the wire on each side of it.

(4). I then tried a stronger tube which I had been using for insulation. It had a bore of $\frac{1}{4}$ inch, and was $\frac{1}{2}$ inch in external diameter. It was capable of sustaining a pressure of probably 10,000, and certainly 5,000 lbs. on the square inch; that is to say, a pressure of from 2 to 5 tons per square inch. It was about 14 inches long, and bent in the form of a square-ended syphon. The gap in the wire was about $\frac{1}{4}$ inch, and the water extended about 14 inches on each side of the gap. The ends of the pipe were open, and the jar charged in the same manner as before with about 100 turns of a 12-inch plate machine. The surface of the jar is about half a square foot, and the discharge, when effected with the common rod, took place through about 2 inches of air.

This tube was shattered at the first discharge. That part opposite the gap and for some way beyond is completely broken up into fragments which present more the appearance of having been crushed by a hammer than of being the fragments of a pipe burst under pressure. Some of the fragments show that the interior of the pipe has been reduced to powder.

These fragments were scattered to some feet on all sides, but there was nothing like an explosion. I held the pipe in my hand at the time of the discharges, and the sensation was that of a dead blow. There was no noise beyond the ordinary crack of the discharge.

The manner in which this pipe was destroyed clearly showed that a larger one might have been broken. But as it was two o'clock and my fire was out, I did not continue the experiments.

It is not easy to conceive the precise way in which a pressure of probably more than 2000 atmospheres could be produced and transmitted in a pipe of water the ends of which were open. It might have been caused by the sudden formation of a very minute quantity of steam, or by the expansion of the water; but whichever way it was, its effect was due to its instantaneous character, otherwise there would have been an explosion.

When we consider the great strength of this pipe (which might have been used for a gun without bursting), and when we see that it was not only burst, but that the interior of the glass was actually crushed by the pressure, and all this by the discharge of one small jar, we must cease to wonder at the bursting power of a discharge from the clouds.

NOTICES OF BOOKS.

The City Record. Vol. I., No. 51. (Official Journal). New York.

THIS journal is an American "institution," which might with great advantage be imitated in England. It is a Quarterly Report of the "Health Department" of New York. The reader finds in it a list of the various sanitary officials; a record of their proceedings; notices of changes in laws relating to public health; remarks on inhabited cellars, on street cleaning; street pavements, street garbage, sewerage and drainage, wharves and piers, public markets, slaughtering, fat-melting, stable manure, and night scavenging; removal of night-soil from the city; removal of dead animals, offal, &c.; manufacture of gas; permits; disinfection and disinfectants; impending pestilence, with special notes on the prevention of cholera; city mortality; bureau of vital statistics; sanitary bureau; expenditure of the Health Department; and an official directory. This paper is commonly sold in New York, and any person who wishes to satisfy himself as to the doings and the efficiency of the Health Department can purchase a copy. The nearest representative of this Record in London is the Report of the City Commissioners of Sewers. But this "Report," unlike its American contemporary, is not printed for general circulation; a few copies only are struck off for distribution to official personages. Editors of influential journals may succeed in procuring copies, but to the public they are practically inaccessible. Believing that, as far as sanitary matters are concerned, the Metropolitan Board of Works has not quite reached perfection, we should very much like to see a similar "Record" issued here. Perhaps, as a necessary preliminary, a new sanitary authority would be needed, consisting of men of a somewhat higher intellectual type than the nominees of the vestries.

Under the head "Disinfectants," we learn that the substances most in favour in New York are—Chlorides of zinc, iron, and of manganese; sulphate of zinc; carbolic and cresylic acids. The latter fluids are particularly recommended for the disinfection of drains, cesspools, privies, &c., on the approach of cholera.

CORRESPONDENCE.

INCOMPETENCE OR WORSE.

To the Editor of the Chemical News.

SIR,—In the interest of those of your readers who have a good deal of money staked on the honesty and accuracy of assays of raw material, I send you the following little statement of fact.

A firm of commercial analysts, acting for an importing house who recently delivered me a large consignment of phosphate, return as their assay of it "phosphoric acid 37.27 per cent, equal to tribasic phosphate of lime 82 per cent."

My chemist, finding their result a good deal higher than his own, was led to examine their certificate, and, immediately perceiving its inaccuracy, wrote to them asking for an explanation of their calculation. He received no reply to his letter, and the sellers coolly maintained that their chemist's result was correct, being calculated according to the universal usage of the trade!

In the face of my firm protest, they were instructed to assay a subsequent consignment, and their return of that was "phosphoric acid 38.11 per cent, equal to tribasic phosphate of lime 84 per cent." The sellers have since shown me a letter from them, in which they say that they "take 28 as the equivalent of lime, 70 as that of phosphoric acid, and 154 as that of the tribasic phosphate of lime" (!).

As, however, these "equivalents" only apply to their first assay, and their atomic weights for the second have not been communicated to me, perhaps some of your readers can help me out of my dilemma. Seriously, I am asked upon the first cargo to accept an assay return based on "equivalents" which make an amount in money over that of the real equivalents by some £13 to £14. For the second lot, a return is handed me which gives £14 to £15 over the true value, £11 to £12 of this being doubtless explained by the "equivalents," and £2 to £3 by a slovenly error in the calculation which would discredit any boy in our elementary schools.

I need not comment further on this *chef d'œuvre* of commercial assaying, when I say that the sellers have since withdrawn their invoice based on the "equivalents," and substituted another calculated properly from the phosphoric acid. I have, however, of course refused to recognise or respect the assays in any shape. To say nothing of the probability of the phosphoric acid itself having been calculated with home-made "equivalents," the way in which the decimals are burked is enough to take away one's breath. Even the first decimal is wrong; and every tyro amongst your readers will know that in the case of a cargo of phosphate at present prices the third decimal represents a considerable money value: what is said of the tricalcic phosphate applies, of course, with still more force to the more valuable phosphoric acid. I dwell on this because I have of late observed a tendency in other quarters to neglect that scrupulous care and exactitude which should characterise the work of every chemist. Certainly "work" such as I have here instanced cannot be too strongly reprehended. Manufacturers and consumers have surely sufficient cause of annoyance in the great discrepancies between honest analyses without the deliberate introduction of false equivalents. All, therefore, who are interested in the integrity and accuracy of assays and analyses, and in the maintenance of our English commercial morality and honour, should unite to put down this kind of thing with a firm hand.

I confess that, on public grounds, I have been very strongly tempted to publish the names of the offending parties. If, however, a milder course than an *exposé*, which would simply finish their reputation, will suffice to stimulate and maintain that strong public opinion which must alone make such practices impossible, I shall only be too glad, as I have no personal animus in the matter.

With regard to the other parties to the transaction—the commercial house (and one, too, whose name is very widely known)—I should have been disposed to attribute their action in the matter to sheer ignorance. That, however, cannot be fairly said of them. They would, at all events, very strongly resent the imputation. They are known as men who pride themselves very much upon their trade knowledge and experience, and are, in fact, continually laying down the commercial law upon any matter. I think, Sir, I must leave them to assess their own motives in this discreditable transaction.—I enclose my card, and am, &c.,

VERITAS.

HYDROGEN AND SOLUTION OF NITRATE OF SILVER.

To the Editor of the Chemical News.

SIR,—It would appear from a note by Mr. Wanklyn in the last number of your journal, that some remarks which I made at a recent meeting of the Chemical Society, *apropos* of Dr. Russell's paper "On the Action of Hydrogen on Silver Nitrate," have been erroneously reported. It is implied by Mr. Wanklyn's note that I asserted that the solubility of hydrogen in water diminishes with rise of temperature. What I did say was, although it is well known that hydrogen is equally soluble in warm and in cold water, it would be interesting to ascertain whether or not such uniformity prevails in its solubility in saline solutions, such as the silver nitrate.—I am, &c.,

A. W. WILLIAMSON.

University College, London, W.C.,
Dec. 8, 1873.

IRON FILINGS IN TEA.

To the Editor of the Chemical News.

SIR,—Permit me to add a few words to the observations of Mr. W. M. Williams, contained in your last number, upon the above subject. It is now more than two months since I discovered that the so-called iron filings tea contained no iron filings whatever, and from that time I have been attempting to inform the public of the fact. On October 22, I wrote a letter upon the subject to the *Morning Post*, but the editor of that paper did not think proper to publish my letter. Up to this time I had examined seven samples of the said tea, but all had been supplied by persons interested in the trade. It seemed to me then necessary, before making further efforts to publish my results, that I should examine an incontestably genuine sample of the tea, said to contain the filings. To procure this tea, I applied on November 1 to a gentleman who holds a high official position in the Corporation, but whose name I decline to publish. This gentleman most willingly undertook to serve me, though his efforts were unsuccessful until Nov. 17, when he forwarded me a genuine sample, duly marked "Tea adulterated with a large quantity of iron filings and sand." This tea, like all the other samples which I had examined, contained neither iron filings, iron turnings, nor metallic iron in any shape or form whatever. Like the rest, it contained magnetic iron ore and granitic quartz. On Nov. 19, I sent a letter stating this fact, and giving the exact composition of the tea, to the *Daily News*, but my letter was not published. On the 22nd, I sent a similar letter to the *Grocer*, with the same result. On the 24th, I sent a letter to the enterprising proprietor of the *Daily Chronicle*, and he published my account of the tea on Wednesday, Nov. 26.

With regard to the iron ore, there is a curious circumstance worthy of notice at present in it. The ore is not hæmatite, as Mr. Williams supposes, for it is attracted by the magnet. It is magnetic iron ore, and contains a large portion of phosphate of iron, so that it never could be converted into malleable iron, and consequently never has

been, nor ever can be, in the state of iron filings. The granitic quartz is mixed with particles of feldspar, mica, and a few fragments of hornblende; it no doubt constitutes the matrix of the iron ore, and thus comes to be associated with it on the tea, where, however, it is a manifest adulteration to the extent, I believe, of 25 per cent. And here let me offer a remark upon tea adulteration; I have found $6\frac{1}{2}$ per cent, $12\frac{1}{2}$ per cent, and 25 per cent, in different samples of black and green tea, as if the Chinese adulterative mind worked by doubles, and not by decimals; thus, the above amounts of adulteration are $\frac{1}{2}$, 1, and 1-16.—I am, &c.,

LEWIS THOMPSON, M.R.C.S., &c.

IRON FILINGS IN TEA.

To the Editor of the Chemical News.

SIR,—In answer to Mr. W. M. Williams, I may remind him that I concluded that the magnetic particles were genuine iron filings from their solubility "in nitric acid with effervescence" (magnetic oxide being scarcely soluble in nitric acid). Certainly the reduction of copper is a more reliable test, but it did not occur to me to use it. By using the term "real lumps of metal," I did not intend to give the idea of great size, but merely to convey the impression that the particles were greatly larger than filings—probably as large as any of the type used for the title of Mr. Williams's letter.

As to your correspondent's question, "Were these found in the ash or in the unburnt tea?" I may express my astonishment that the published reports show that the chemists examined at the recent Birmingham trials looked for the iron filings in the ash of the tea. The method I have employed has been to powder the tea, and spread it out in a thin layer on a plate. A small electro-magnet has then been passed through it, and the attracted particles treated with hot water, which disintegrates the lumps, and allows the ferruginous matter to subside. The liquid being decanted, the deposit has been weighed, and further examined by the microscope, nitric acid, &c.

The tea in which I found the "lumps" of iron was examined some six months ago from curiosity. On my friend asking for some of the "rough flavoured, thick, sappy, Moning congou" described in the window-bill, the shopman added a portion of tea from a separate canister, and, on reaching home, this was readily picked out from the rest by its different appearance. It weighed about 5 per cent of the total quantity, and, besides the lumps of iron, contained sand, starch, magnesia, and plumbago. The percentage of tannin in it was 20 per cent, while even genuine black tea does not contain more than 14 or 15 per cent at the outside, a fact which I considered conclusive of the presence or catechu or other extraneous tannin matter. It will be evident, therefore, that the weight of metallic iron was not very large—probably 2 per cent of the whole tea; it was not actually estimated. The main bulk of the sample contained leaves other than tea, a considerable quantity of ferrous sulphate, and only about 5 per cent of tannin. I think these facts will be sufficient to convince Mr. Williams of the desirability of looking after the tea sold. As a matter of fact, the grocers are perfectly aware of the kinds of tea most frequently adulterated, and understand the use of a magnet and hot water as well as we do.

In his postscript, Mr. Williams calls attention to the summary of the magistrates on the Birmingham tea cases, and considers that the evidence is a strong confirmation of his theory of the origin of the iron detected in tea. At any rate, the magistrate thought differently, and, in the face of the fact that genuine teas contain neither magnetic matter nor insoluble silica, could not do otherwise than conclude that these substances had been purposely added to the teas found to contain them.

If Mr. Williams will look again at my letter, he will see that I suspect the English tea-dealers of the addition of

sulphate of iron, not metallic iron, though I remain unconvinced of the difficulty of obtaining the finely divided metal when wanted. At the same time, I fully admit that in the majority of cases the ferruginous matter consists of oxide or titanate of iron, and no doubt was added by the Chinese, probably in accordance with the instructions of the agents of the English merchants.—I am, &c.,

ALFRED H. ALLEN.

PS.—In my last letter, for the words "cayenne to give a sulphuric acid to vinegar," please read "cayenne to give a sulphuric acid to vinegar."—A. H. A.

Sheffield, Dec. 6, 1873.

IRON FILINGS IN TEA.

To the Editor of the Chemical News.

SIR,—I thought that the "figment" of iron filings being in "tea" was finally set at rest by the decision of the "Stipendiary" in the late tea prosecutions at the Birmingham police-court, but, from what I see in your last two numbers, it is again beginning to be debated.

Having had the management of the chemical defence, it has occurred to me that it would be useful briefly to state the "reasoning," founded on experiment, why I came to the conclusion that not only were there no iron filings in the suspected tea, but that tea is never adulterated with iron filings,—that it is a libel on the Chinese to say that they ever put any in, and I am certain that none would be more astonished at the "charge" than the Chinese themselves.

The certificate given by the analyst of this borough stated that the tea was adulterated with "iron filings, sand, and earthy matter." As to the two last, the analyses of the tea, made by myself and colleagues (Dr. Wrightson, Prof. Murphy, Mr. Horner, and Mr. Scott), showed that this was so, and, finding that the tea stuck to the magnet, I thought, with the "analyst," that there were iron filings in it. But, considering that the Chinese have no vast fitting shops, as we have here, I wondered where they could get the iron filings from; I therefore thought it of great importance to get the iron filings out as iron filings, to do which I reduced the tea to powder, and then made it into a paste with strong alcohol; when this had been dried out, I searched the powder with a magnet, and attracted out some dark brown particles, which formed a "brush," just like iron filings would at the poles of the magnet. On examination, the particles turned out to be magnetic oxide of iron, but there where here and there little brilliant facets of something having a metallic look, which stuck to the magnet with the magnetic oxide, which seemed to me to indicate that the Chinese made a mixture of iron filings and magnetic oxide of iron to dose their tea with.

Up to this moment, therefore, I thought the borough analyst's certificate was correct; but, pondering on the matter, I put the brown magnetic oxides and sparkling particles on a sheet of paper, and, on viewing them with a "magnifier" in a good light, I thought I observed one shining particle which looked somewhat transparent. I then carefully separated it from the magnetic oxide, and, having detached every trace of the magnetic oxide from it, I found that the shining particle did not bounce to the magnet; it was, in fact, a small fragment of quartz, and some of the particles turned out to be mica.

In order to determine if there was any metallic iron at all, I treated the magnetic oxide with dilute hydrochloric acid, in which acid it dissolved without the least effervescence of hydrogen gas, which would have been the case if there had been a trace of metallic iron present, either rusted or bright. I also kept some of the magnetic oxide of iron in a solution of sulphate of copper for five days, without there being a trace of metallic copper precipitated.

Having thus clearly demonstrated that the magnetic oxide of iron is a natural mineral product, the idea occurred

"If the Chinese put it into their tea, what do they put it in for?" for it is as much in green tea as it is in black tea. To answer this, I got out every trace of magnetic oxide from 100 grs. of the tea, and found that it only weighed 0.03 gr., a quantity so small as to be almost invisible, and yet so strongly magnetic was it that the most minute particle adhering to a large leaf (when curled) made it stick to the magnet. It was therefore absurd to suppose that so minute a quantity could be put in for any purpose whatever.

I now proceeded to examine a great number of "magnetic teas," and had London searched for the worst specimens which could be found, one of which was the tea "*ex Sarpedon*," which Dr. Letheby alluded to in his Memorial to the Commissioners of Sewers last April. Dr. Letheby will perhaps be surprised to hear that there is not a trace of iron filings in the "*Sarpedon*" tea; neither is there any in any of the magnetic teas which I have examined; but they one and all contain magnetic oxide of iron, and some of them contain oxide of manganese, doubtless derived from the soil of China. Unfortunately, we cannot examine the soil of China; I therefore examined the soil of many gardens in this neighbourhood, and found that, wherever there is black mould, magnetic oxide of iron is in it. If, therefore, leaves come in contact in any way with the soil, such leaves, when dried, will be attracted by the magnet. I recommend those interested in this matter to dry a few ounces of black mould in an oven, and then search it with the magnet, when the magnetic oxide will be readily attracted.

I have examined the dust of African ginger, Cochin China ginger, East India senna, American hops, chillies from Cayenne, and other vegetable substances from all parts of the world, and they all contain magnetic oxide of iron, but no iron filings.

I just add that the grocers are very sore at the charge about iron filings. They say, "Iron filings neither grow in the ground, nor are they in the juices of plants; if, therefore, iron filings are in tea, in however small a quantity, it must be a fraud, and ought to be punished." My advice, therefore, to the public analysts is to "change front" about iron filings, or they may "catch a Tartar," as was the case in the Birmingham police-court.—I am, &c.,

ALFRED BIRD, F.C.S.

Birmingham Dec. 10, 1873.

ALUM IN BREAD.

To the Editor of the Chemical News.

SIR,—In your last number, Professor Gardner, F.A.S., M.S.A. (and also, as appears from his advertisements, F.S.A., F.E.S., &c.), raises some objection to a late criticism in *Iron* on his aluminised bread analysis. The learned professor suggests that he could only have missed the alum if it had been ammonia-alum. Now, as there happens to be far more ammonia-alum in the market than potash-alum, it is, to say the least, singular that Mr. Gardner should prefer to employ a means which would only detect the kind he was least likely to find.

The principal point in question, however, is as to the volatilisation of sulphuric acid in preparing the ash. Anyone who takes the trouble to collate the published analyses of bread-, wheat-, and flour-ash, will see that the phosphoric acid therein is far more than sufficient to saturate the bases present. Under these circumstances, it is simply absurd to expect sulphuric acid, if present, to remain undecomposed in such an ash after ignition. Mr. Gardner, it seems, does expect a sulphate to be stable under these conditions. It appears, then, that he has made either an important discovery or a serious mistake. I, with many others, adopt the latter conclusion; and the Polytechnic professor would have shown himself wiser and more manly by confessing his error.—I am, &c.,

THE EDITOR OF "IRON."

Dec. 9, 1873.

CONCERNING ATOMS.

To the Editor of the Chemical News.

SIR,—Your correspondent "Atom" (CHEMICAL NEWS, vol. xxviii., p. 281) has stated that the existing difference of opinion amongst chemists, on the subject of Atoms, appears to arise from our incapacity to understand the meaning of "the infinitely small."

Now, with respect to space, I think a clear *positive* idea of the infinitely small is to be found in the mathematical definition of a *point* (having neither length, breadth, nor thickness). It exists in space (we may term it a *locus* in space), but has no extension, so that the addition of points (even *ad infinitum*) can never produce any finite space, however small.

I think the most determined opponent of the atomic theory will hesitate, however, before he attempts to apply the same argument to *matter*; and, if it be not applicable (that is to say, if matter must have *extension*), it appears clear that "matter cannot be divisible *ad infinitum*," which demonstrates the truth of the atomic theory, although it does not, of course, prove that in any case we have actually arrived at the ultimate division, even in theory.

With respect to "the infinitely great" it is utterly impossible to attain any *positive idea*; our nearest approximation is by a mental process of "increasing the finite without end,"—a pure negative notion; but in regard to two points we can be perfectly certain, viz. (1), that additions of the infinitely small can never produce anything finite; and (2), that additions of the finite (however large), even *ad infinitum*, cannot produce the infinitely great.

In fact, "the infinite" can never be either a multiple or sub-multiple of the finite.—I am, &c.,

HENRY HUDSON, M.D.

Glenville.

THE CHEMICAL SOCIETY'S NEW ROOMS.

To the Editor of the Chemical News.

SIR,—I am sure that such of your readers as are accustomed to attend the meetings of the Chemical Society will join with me in protesting against the bad lighting and ventilation of their new rooms.

The height to which the seats are raised, in so comparatively low a room, exposes their unfortunate occupants to a blinding glare and overpowering heat from the sun-lights overhead; and this, added to the bad state of the ventilation, renders the room dangerously unhealthy; indeed, speaking of one or two friends, I can testify to its evil effects.

The room ought to be lighted by brackets, at least at the upper end, and better ventilation provided. At all events something must be done.—I am, &c.,

VENTILATOR.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 3, 1873.

Certain Calorimetric Values and Problems.—M. Berthelot.—The author announces the agreement of the

results obtained by MM. Favre and Valsen with his own. The only discrepancy, the case of borax dissolved in sulphate of ammonia, he explains by means of a double decomposition which takes place. Supersaturation he views as the slow formation of a new hydrate. Perhaps the existence and the disappearance of a great number of saline supersaturations express merely the existence and transit from one definite stage of hydration or of combination to another representing a lower degree of solubility.

Researches on the Thermic Effects accompanying the Compression of Liquids.—P. A. Favre and Laurent.—A mere preliminary notice "to take date."

New Volatile Saccharine Matter Extracted from the Caoutchouc of Madagascar.—Aimé Girard.—The author recently (Comptes Rendus, lxxvii., p. 820, and lxxiii., p. 426) described two new volatile and saccharine matters, dambonite, $C_8H_8O_6$, extracted from the caoutchouc of the Gaboon; and bornesite, $C_{14}H_{14}O_{12}$, obtained from the caoutchouc of Borneo. Both these, on treatment with hydracids, are split up into methylic ethers on the one hand, and into crystalline non-volatile saccharine matters on the other, possessing the composition of dried glucose. A third substance of this kind, matezite, obtained from the caoutchouc of Madagascar, is white, crystalline, very soluble in water, less so in alcohol, from which it separates in the form of mamillary crystals, hard and gritty under the teeth. It fuses at $181^\circ C.$ to a vitreous mass. At 200° to 210° it sublimes slowly without decomposing; the sublimate does not take the form of needles, but that of transparent drops. It consists of—

Carbon	42.3
Hydrogen	7.0
Oxygen	50.7

100.0

Its formula is $C_{20}H_{20}O_{18}$.

Preparation of Active Amylic Alcohol.—J. A. Le Bel.—There appears to exist an inactive amylic alcohol boiling at $29^\circ C.$, the constitution of which is well known, and an active alcohol, having a rotatory power of about 20° for a column of 50 centimetres. The latter alcohol has been less studied on account of the difficulty of its preparation. It boils, according to Pasteur, at 27° to 28° . It is deprived of its rotatory power by repeated distillation with potash.

Influence of Certain Gases on the Preservation of Eggs.—F. Crace-Calvert.—Oxygen in a dry state has no perceptible action. If the gas is moist the egg becomes covered in three weeks or a month with a white mouldiness, consisting of *Penicillium glaucum*, or of a *Mycelium*. On breaking the egg its contents do not appear to have undergone any decomposition; though an examination of the gases in the apparatus reveals the presence of a notable quantity of carbonic acid and of a little nitrogen. If the shell is perforated with a fine needle the egg is decomposed in dry oxygen, liberating a larger quantity of nitrogen and carbonic acid. There is a little *Mycelium* on the outside of the shell, and the contents, which are putrid, contain abundance of vibriones and mycozymas. In moist oxygen the decomposition is more complete. In moist nitrogen, eggs, whether perforated or intact, may be kept for three months. If perforated, the contents are slightly decomposed; no filament of *Penicillium* can be seen, but vibriones are formed. In hydrogen the eggs are covered with a slight down, but the interior remains sound. In carbonic acid the eggs are preserved perfectly, and the shells do not show any trace of *Penicillium*. In coal-gas the results are similar.

Influence of Certain Substances upon the Preservation of Eggs.—F. Crace-Calvert.—The author plunged new-laid eggs in weak solutions, $\frac{1}{10}$ of chlorine, hypochlorite of lime, sulphite of lime, and phenic acid. Eggs in a solution of chlorine, in a stoppered bottle, remained unchanged from April 18th to December 12th

On being withdrawn from the solution and re-inserted, the bottle being left unstopped, they were found on the 19th of December covered with *Penicillium glaucum*. In chloride of lime the eggs were found covered with *Penicillium* on April 28th, which continued to increase. On June 8th, it could be seen through the shell that the yolk was displaced, and numerous filaments of *Penicillium* appeared in the interior. In lime-water the eggs became covered with *Penicillium* in twenty days, and on June 8th, other forms of mould appeared in the interior. The contents were decomposed, the white containing much *Penicillium*, and the yolk abundance of microzymas. Sulphite of lime gave the same results. The eggs plunged in phenic acid presented no change up to June 8th. They were then slightly covered with mould, but the contents were quite sound.

On Malaria.—M. L. Colin.—The author concludes that the soil plays an important part in the generation of malaria; that the ingestion of marsh-water does not produce intermittent fever; that it will be easier to discover the febrigenous germs on the surface of land newly turned up than in the atmosphere of the marshes.

Analysis and Criticism of an Essay on the Constitution and Origin of the Solar System, by M. Roche.—Note by M. Faye.—M. Roche, supplementing La Place's theory, has studied the surfaces of level beyond the actual limits of atmospheres. He shows that, commencing from a certain distance, these surfaces cease to be convex towards the centre of the star. They merge into one another, and present infinite sheets, so that extending (in thought) the actual atmosphere of one of our planets to those regions of instability, the materials are no longer held by gravity to the star, but are dispersed in space along those surfaces. M. Roche deals with some difficulties attaching to La Place's theory. Saturn's rings, e.g., are half contained within the actual limit of the planet's atmosphere, that is, in a region where it would be impossible (La Place's notions being rigorously accepted) that this atmosphere, in contraction, would have left these matters; whereas if it dilated, it might exist up to the half of their breadth. Other difficulties are the great distance of the moon from the earth, the gap between Jupiter and Mars, the multitude of asteroids (135 now known) in place of a single planet; then (coming sunwards), the formations so different from those beyond,—very dense planets with slow rotation.—M. Roche has treated such problems with the aid of a new conception. La Place, e.g., only supposed rings frequent beyond the limit where gravitation towards the sun equilibrated centrifugal force. M. Roche shows, by the discussion of his surfaces of level, that the portion of the nebulous matter liberated does not merely come from the equator, but from a superficial sheet which extends much further towards the two poles, and which tends to flow towards the equatorial opening. Now, certain parts arrive with a velocity insufficient for their circulating exteriorly; they then return to nebulousity, describing ellipses, the apelia of which are precisely at the equatorial limit. This being premised, M. Roche points out that, through the resistance of the medium, a portion of those materials ultimately falls to the sun, restoring to it some heat, while others merely lose, by their mutual reactions, their radial velocities, but retaining for the most part their tangential velocities. This idea of interior rings rendered free, in their turn, by the progressive contraction of the generating atmosphere, supplies M. Roche with the explanation of a part of Saturn's rings forming where, according to another law, no satellite of the same density as the planet could form. M. Roche's original ideas are these: Equality of duration, at first, in the rotation and the revolution of each planetary mass; impossibility of formation of satellites so long as the solar action could maintain this equality; possibility of such formation whenever the contraction of the limiting surface of the atmosphere has reduced the directive force of the central star; formation

of interior rings at the limiting surface; condition in which a planet, or a fluid mass, may conserve its figure of equilibrium, spite of the formation of the central body. (The distance should not be below five-fourths of the quotient of the diameter of the latter divided by the cubic root of the density of the satellite). M. Faye warmly commends M. Roche's work.

Mutual Action of Voltaic Currents.—M. Bertrand.—In 1871, M. Helmholtz proposed a new formula to replace Ampère's law on the elementary action of circuits. M. Bertrand considered the new law did not correspond to any force of determinate strength and direction operating between two elements, and that it must be rejected. M. Helmholtz recognised that no force, according to his law, would represent the action of an infinitely small element on an infinitely small element; but he does not see here a decisive argument against his theory. The action of two elements is composed of a force and a couple acting on each of them, and this, in his opinion, does not involve contradiction. But (urges M. Bertrand), following out such principles to their conclusion, and calculating the moment of the couple, one finds that the force producing it must have a finite intensity. Whatever the tenacity of a wire, an infinity of forces of finite strength distributed throughout its length must produce rupture. M. Bertrand here reproduces a memoir, in which M. Helmholtz has lately, in the Berlin Academy, returned to the question; and proposes shortly to reply to it.

Verification of the Areometer of Baumé.—MM. Berthelot, Coulier, and D'Almeida.—The authors give some numerical data towards establishing the graduation of the instrument. The saline solution serving as type in the areometers was prepared by dissolving 15 parts of pure chloride of sodium in 85 parts distilled water weighed in air with brass weights (the pressure being 0.760 m. and the temperature 12.5°), 1 litre = 1110.57 gr. Next, as to the production of 1 litre vessels at a temperature of 12.5°, the authors show that the 1 litre vessels constructed at 15°, under the supposition that each contains 1000 grammes of water, weighed in air, are too large by about two-thousandths.

Observations of Solar Protuberances (continued) During the Last Six Rotations of the Sun, from 23rd April to 2nd October, 1873; Consequences as to the Theory of Spots.—P. Secchi.—This series shows a considerable decrease in the number of eruptions. While in the first series of 1871 the number was, on an average, 14 or 15 daily, with maxima of 20 to 23, and minima which rarely descended to 10, the last rotations give an average of 8 or 9, and the maxima do not exceed 12, while the minima are 4 or 5. The spots are also less numerous. From the longitudinal distribution of protuberances, it appears that some meridians give distinct minima and others maxima. Opposite points on the east and west borders often show agreement, a diametrical distribution apparently; but these details disappear in the averages. The metallic eruptions have been few and very intermittent; one, on the 18th Sept., was very memorable, and produced a group of spots. The author finds confirmation of his theory of spots. To the statement that there appear eruptions without spots he replies—(1) That these cases are very rare; (2) that the eruptions are weak, and the (comparatively) small masses projected are immediately dispersed; (3) he has noticed that certain metals have a greater efficacy (in production of spots) than others. Thus the eruptions charged with sodium give very pronounced spots; magnesium is less efficacious, and there are often beautiful eruptions of this metal without very dark spots. The cases of spots without eruptions have not been rare, but there have been few of them on the east side. Father Secchi remarks on the sheaf form of some of the protuberances, and gives a sketch. As to the direction of protuberances, he always found, in the high latitudes, the dominant direction is towards the

poles; in low, towards the equator; the change of direction occurring at about 40° . In calm periods there is a somewhat different system of directions from what is found in periods of activity.

Report on a Memoir of M. Graeff on the Application of the Curves of Discharge to the Study of the Régime of Rivers, and to Calculation of the Effects Produced by a Multiple System of Reservoirs.—MM. Phillips.—M. Graeff shows that the effect of a single reservoir in a neighbouring region down the stream is certain, and may be exactly estimated; that the effect of several reservoirs on the same water course is also certain, though less easy to appreciate; and, lastly, that where there are at once reservoirs on the principal watercourse and on its affluents, the uncertainties increase so much that this system is not advisable, unless in quite special cases.

Influence of Atmospheric Refraction at the Instant of Contact in the Transit of Venus.—M. Oudemans.—The author shortly criticises a note of M. Dubois, and thinks that, in any case, the influence of refraction must be less than 0.13 s.

Frigorific Effects Produced by Capillarity Combined with Evaporation; Evaporation of Sulphide of Carbon in Porous Paper.—M. Decharme.—Reserved for translation.

Remarks on Various Practical Problems of Aërial Navigation (Extra).—M. de Fonville.—The author thinks it highly probable that the gas of a free balloon differs in temperature from the external air by 10° C., at least twice daily. This rupture of thermal equilibrium must limit its course to a very small number of days; independently of other disturbing causes, it would render a passage across the Atlantic impossible. Nor can the disturbance be obviated by closing the orifice of the balloon with a hermetic valve. A small balloon of transparent caoutchouc explodes loudly when merely pierced with a pin; this is due to the surprising rapidity with which the membrane is rent, although the pressure of the hydrogen does not greatly exceed that which would obtain within a large free balloon, where it might be sought to neutralise the effects of the solar dilatation. Nor would the greater resistance of envelope obviate the disaster. M. de Fonville also remarks on the despatching of pigeons from balloons at regular intervals, on the disastrous voyage of Mountain and Bailey, and other topics.

Note on the Best Dimensions to give to Electromagnets.—M. du Moncel.—The writer constructs a formula from which flow some important conclusions; more especially (1) That for resistance of equal circuits, the diameters of an electro-magnet should be proportional to the electromotive forces; (2) for equal electromotive forces, the diameters should be in inverse proportion to the square root of the resistance of the exterior circuit, including the resistance of the battery.

On the Recent Eruption of Nisiro.—M. Gorceix.

Bulletin de la Société Française de Photographie,
No 10. 1873.

This number contains a continuation of M. A. De Constant's paper on the dry collodion process.

Modification of the Collodio-Bromide of Silver.—J. F. Plücker.—The author remarks that this process is the most simple known, and yields results as good as, if not better than, those of the iodide and the silver bath. It has, besides, the advantage of rapidity in the preparation of sensitive surfaces, and that of avoiding the use of a costly solution of nitrate of silver. The development of the image is very regular. The sensibility in respect to objects which reflect abundance of chemical rays is the same as that of surfaces of iodide and iodo-bromide of silver, but it is greater for feeble rays such as those issuing from verdure-shaded parts, &c.

Preparation of the Bromised Collodion.—Dissolve in 100 c.c. of alcohol 2 grammes of bromide of cadmium and 0.5 gramme bromide of ammonium; add to the mixture 2.5 grammes of papyroxyl (paper converted into nitro-cellulose) and 150 c.c. of sulphuric ether. Introduce into the solution 0.8 gramme of yellow gum-lac in scales, which is dissolved by the aid of the water-bath. Finally, 4 drops of pure nitric acid are added. After resting from two to three weeks, the collodion is ready for use. To render this collodion sensitive, an hour before the layer is required, the following solution of nitrate of silver is required. Put into a test-tube of about 12 centimetres long and 15 millimetres in diameter, 1 gramme of crystallised nitrate of silver in fine powder, and 4 c.c. of rectified alcohol, to which 1 drop of distilled water is added. The mixture is carefully heated till the nitrate is dissolved, and the solution is immediately poured into 50 c.c. of the above described collodion decanted previously into a small wide-mouthed flask. This operation is performed in the dark. It is well shaken for some seconds, let settle for an hour, and the emulsion decanted into a second bottle. The plates are covered with the collodion thus prepared, the excess being each time allowed to flow back into the bottle. The prepared plates are washed with rain-water, so that they may be quite free from undecomposed nitrate of silver, and are then set to dry, or before drying they may be coated over with some preservative, such as tannin, dextrin, acetate of morphia. The backs of the plates should be coated with some black or yellow colour. **Development.**—After having softened the sensitive layer by the aid of a mixture of equal parts of ether and alcohol, the quantity of water necessary to cover the plate is put in a developing glass, and a few drops are added of an alcoholic solution of pyrogallollic acid containing 15 per cent, and a drop of an aqueous solution of carbonate of ammonia of 10 per cent.

Process for Preventing Solutions of Gum-Arabic from Moulding.—M. Hirschberg.—A little concentrated sulphuric acid is added, which precipitates the lime present. Solutions treated in this manner have been kept for eighteen months without losing their adhesiveness, or growing mouldy.

The bulk of the papers in this number are from English sources.

NOTES AND QUERIES.

Cigar Ash.—In the analyses of cigar ash by A. Percy Smith, F.C.S., in the *CHEMICAL NEWS*, vol. xxviii., p. 262, the component parts represent only 94.236, instead of 100.00 as stated.—W. SIMMONDS.

Insoluble Gelatin.—In the *CHEMICAL NEWS*, vol. xxviii., p. 109, there is a short paragraph on the power of bichromate of potash to make gum, gelatin, &c., insoluble. Can you inform me where I can ascertain particulars as to the mode of procedure, quantities to be used, &c.?—JAMES BARCLAY.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 15.—Medical, 8.

TUESDAY, 16.—Civil Engineers, 8.

— Anthropological, 8.

THE CHEMICAL NEWS.

Vol. XXVIII. No. 734.

ON A NEW METHOD FOR PRODUCING THE ANHYDROUS CHLORIDES OF ALUMINIUM AND OTHER METALS.

By PAUL CURIE.

THE only published process for the production of aluminium chloride is the well-known method of sending chlorine through a mixture of pure alumina and charcoal, heated to redness. The following is, I believe, a simpler method, which might perhaps, in many respects, prove economical for the manufacture of aluminium, as it does not require the use of pure alumina, nor the preliminary calcination of the same with charcoal. This process is based on the transformation of alumina into sulphide of aluminium, and subsequently of the sulphide into chloride, which two operations are condensed into one by the means hereafter described.

Sulphide of Aluminium.—This is obtained by heating alumina in a tube or retort, through which are sent vapours of bisulphide of carbon, the reaction which takes place being expressed thus:—

Sulphide of aluminium then remains in the tube or retort. The gases which escape are mostly COS, though a portion of that oxysulphide of carbon is decomposed on account of the too great heat; there is therefore, also, a certain quantity of sulphur and of CO.

Sulphide of aluminium is not easily converted into chloride, as might be thought, by double decomposition with the chlorides of other metals: thus, with NaCl only a very small quantity of chloride of aluminium is produced; with CaCl, MgCl, none at all; with KCl it forms a volatile compound, containing KCl, KS, Al₂S₃, and Al₂Cl₃; but by hydrochloric gas, HCl, the chloride of aluminium is readily produced.

To effect the conversion of alumina into chloride of aluminium, by a single operation, this is how I proceed:—The alumina is placed in a porcelain or earthen tube, and heated to redness. As soon as all the water is expelled from the alumina, the tube is connected at one end with a receiver, and at the other end with a tube, bringing in a mixture of hydrochloric gas and sulphide of carbon vapours. By merely sending the HCl gas through the liquid CS₂, it is so thoroughly saturated with it that it is not necessary to apply heat to the latter. A double reaction takes place simultaneously, and chloride of aluminium distils at once, mixed up with a certain quantity of sulphur and impregnated with HS. The aluminium chloride is afterwards re-distilled with iron filings, so as to free it from the sulphur and other impurities.

This process can be easily adapted to the production of all or any of the other metallic protochlorides. I have succeeded equally well in forming magnesium and chromium chlorides.

In order to make a pure aluminium chloride, as I have already stated, it is not necessary to use pure alumina.

Ordinary clay will succeed just as well: in that case the chloride of silicium, which is formed at the same time, escapes as a gas, and the other chlorides formed,—such as those of iron, calcium, &c.—being less volatile than that of aluminium, remain in the tube or retort.

ANALYSES OF TEAS.

By A. S. WILSON.

THE following analyses, made recently, may be useful for comparison. The first seven samples are shipments of last season's teas, and were received direct from the importers. The microscopic examination showed that they were all genuine, although the leaves presented very different appearances, those of the Pekoe being small and thin, whilst those of the Assam were large and thick. Sample No. 10 was ordinary black tea, as retailed, and consisted probably of Moning with a small admixture of Assam and Pekoe. No. 8 represents an Assam green tea, of very fine quality and quite free from facing. No. 9 is China green tea, "faced," but otherwise of fine quality. The facing consists of steatite, or some other magnesian silicate, and turmeric, with an exceedingly minute quantity of Prussian blue.

Several persons have been prosecuted, under the Adulteration Act, for selling faced tea: the result has been that green tea has deteriorated in value, if, indeed, it has not been completely driven from the market.

At a recent prosecution case, in Glasgow, the city analyst stated in his evidence that this tea (No. 9) contained 3 per cent of adventitious substances, but this could only have been intended as an approximation, since there is no means of estimating the quantity of turmeric. In giving evidence for the defence, Dr. Wallace stated that the quantity of Prussian blue did not exceed a tenth of a grain in an ounce of tea; and as green tea is only used for mixing with black, and seldom to the extent of more than 10 per cent, it follows that an individual is not likely to consume at one time—even supposing the whole of the pigment to become suspended in the infusion—more than the two-hundredth part of a grain of Prussian blue. It was further argued for the defence that, as the added ingredients are not poisonous, and are evidently not introduced for the purpose of adding weight (since the quantity would not pay the expense of the manipulation), the case was not an offence under the Adulteration Act. The vendor, however, was fined for selling it, and fines have been imposed on several others since then for the sale of tea of a similar kind.

In the following table A represents the percentage of ash; B, the proportion of the ash soluble in water; C, that soluble in hydrochloric acid; D, the siliceous matters; and E, the amount of peroxide of iron in the ash.

	A.	B.	C.	D.	E.

Perkin and Son.—We understand there has been recently a movement on foot for converting the concern of Perkin and Son, the great patentees and manufacturers of alizarin, at Sudbury, into a Limited Liability, with a paid-up capital of £200,000. We learn, however, that the entire business and patents have just been purchased for a very large sum by Brooke, Simpson, and Spiller, the well-known London manufacturers of aniline colours.

the case, the earth at the Equator, getting more heat than at the Poles, gives its heat more abundantly to the water, and swells the water, and that swollen water is carried to the Poles: there is something illogical in this, because the swollen water is not heavier than the unswollen water. Then the explanation has been given that it is owing to the prevailing winds at the Equator. But, speaking under correction, I imagine that the origin of the Gulf Stream is rather to be looked for at the Poles than at the Equator. When water freezes it gets lighter: a quantity of water freezing at the Poles has the result of a lifting of water above the water, and the leaving of a quantity of brine, the same temperature as the ice at the moment of freezing, but denser. The heavy brine therefore sinks, and travels from the Pole to the Equator beneath the general mass of the water, and this current has to be compensated for by the travelling of warm water at the surface from the Equator to the Poles, which finally encounters and melts the ice-floes moving in the opposite direction. Thus, modified by the winds, and guided by the contour of continents, it tempers our climates so materially and, for us, so essentially, having for a return current that current at the base of the ocean which we seldom can recognise but by the deepest plumbing.

With regard to the conduction of heat by gases the whole system of ventilation depends upon it, and also upon the elementary fact that all gases swell by heat, and therefore, if a hot mass of gas is imbedded in a cold mass of the same gas, it has a tendency to rise.

And now we come to a point which requires considerable power of abstract reasoning to see it clearly, and therefore the simplest illustrations possible will be used. Different substances have different capacities for heat, *i.e.*, if we take equal weights of two different substances at the same temperature, and put the same quantity of heat into each, we shall find them in most cases to be unequally heated; or, if we take the same quantity of heat out of each, the one which was before heated most is now cooled most. We may aptly compare the capacities of different bodies for heat with the capacities of different cylindrical vessels for water, comparing the temperature with the liquid levels. Thus, the level of the water in a wide cylinder will be less affected by the addition or withdrawal of a given quantity of water than the level in a narrow cylinder. Four metals—Fe, Cu, Zn, Bi—are all taken from the same oil-bath, and placed upon the same sheet of wax. The melting power of Bi will be represented by the cylinder having the less capacity for water.

There is, therefore, a most important difference to be observed between the quantity of heat in a body and the temperature of a body. The quantity of heat is measured by the heat-unit, which is generally considered as the quantity of heat which will raise 1 grm. of water at 0° C. to 1° C. It is found experimentally that if a hot body be able to heat 1000 grms. of water 1° C., it will heat 500 grms. 2° C., and so on, proving that the capacity for heat of water is nearly the same at all temperatures.

The ratio between the capacity for heat of one body and the capacity of an equal weight of another body is the specific heat of the first compared with the second. Water is the substance generally taken as having the standard or unit capacity for solids and liquids. Suppose, then, we plunge 1 lb. of a metal at 100° C. into 1 lb. of water at 0° C., and find that the resulting temperature is 12° C., we know that the 1 lb. of metal in falling 88° C. has raised the 1 lb. of water 12° C. The capacity of water is therefore greater than that of the metal, in the proportion of 88 to 12, or the specific heat of the metal is $\frac{12}{88}$, or about 0.14. It must be well borne in mind that specific heat is not heat at all, but number—number got by comparison or division, just like specific gravity. Further, that it is, like specific gravity, independent of the quantity or individuality of the matter under consideration. We are obliged to operate with a certain size and weight of any substance, say copper, but we obtain the specific heat of all pieces of copper—of copper in the abstract.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 287).

SIR H. DAVY, in an article "On the Causes of the Colours of Organic Beings," written about 1790, when Davy was only 19 years of age, writes—"Nature has catenated together organic beings, and made them mutually dependent on each other for their existence, and all dependent on light. A privation of light would be immediately destructive to organic existence; vegetation would cease; the supply of oxygen gas would be immediately cut off from animals; the lower strata of the atmosphere would become composed of carbonic acid; and perception and volition would exist no longer."† Although these views were expressed more than eighty years ago, very little progress has been made in the direction they indicate.

Such considerations as these suggest that he who would truly ascertain and measure the energy of light—that energy upon which all terrestrial life depends—must look to do so in its influence on organised beings; he must either separate the allied influences, or he must so separately estimate these that he can apply his estimate correcting a general result by a process of common occurrence—*viz.*, the eliminating of all foreign or allied energies, and thus give to science the true energy of true light. He who, with knowledge and patient skill, enters upon this hitherto almost unexplored and yet noble field of investigation and research, will give to the age in which he lives, and transmit to future generations, that which will indeed be a boon to all. Pending the coming of that time when some science investigator, possessed of sufficient knowledge, humility, originality, and skill, shall do for light what Newton, Atwood, and Kater have done for the measuring of the energy of gravity—what Mayer, Joule, and Thompson have done for that of heat—what Haughton has done for that of vitality, and what Siemens, Matthieson, Jenkins, and others have done for electricity—what Davy, Dalton, and others have very partially done for that of affinity, and what Bunsen and Roscoe have done for the chemical energy of light—but what no one has yet done for that of light, properly and exclusively so called—we must content ourselves with such modes of estimating this energy as are at present known and available.

This energy is supposed to be manifested in the promotion and facilitating of chemical affinities. These affinities (as doubtless some present remember) vary in their character as one or more of the "imponderables" are combined in their promotion. So much is this the case that chemical notation now adds, in reference to certain indicated changes, the words, by heat or electricity, as the case may be. There are, however, certain affinities called forth under the influences of light which do not show themselves under any other conditions. As, for example, certain of the salts of silver (such as silver combined with chlorine, iodine, or bromine) change their colour and their character, the silver being set free from its combination as a black powder. There is also that power, which plants in the presence of sunlight possess, of changing the carbonic acid gas, which, if allowed to accumulate in the atmosphere, would soon render it unfit to be breathed, into its constituent elements, the plant retaining the carbon and ejecting the oxygen. Priestly, in 1790, that is, at the period when Davy wrote the article from which an extract has been read, a period when, for a short time, men's minds were being directed to this department of scientific research, was the first to show that plants kept the atmosphere pure and healthy, but he

* The Cantor Lectures, delivered before the Society of Arts.

† Davy's Works, vol. ii, p. 106.

could not calculate. His was rather a qualitative, and not a quantitative result.

Changes in the colour of salts of silver, through some energy of light, have been observed since the middle of the sixteenth century. In 1777, Scheele suggested some explanations which, although very imperfect, are as yet the only recognised ones. In the early part of the present century experiments of a similar kind were made at the Royal Institution by Wedgwood and Davy.* The absence of any mode of fixing the impression caused the results to be very evanescent, but the localising of this peculiar property of light is clearly announced in these words:—"Red rays, or the common sunbeam, passed through red glass, have very little action; yellow and green are more efficacious, but blue and violet light produce the most decided effect."

The rapid development of the art of photography during the past twenty or thirty years has led enthusiasts in this branch to overlook the purely chemical character of their art, and to attribute the changes with which they deal to a manifestation of the energy of light. Hence scales have been devised which may enable photographers to adopt some kind of a standard. They are not, however, worthy of the name of scales of energy, as they depend upon the power of the eye to appreciate very slight differences in shade. A scale or measure, to be of general use, should be of such a character that a person in one part of the world writing to one in another might refer to some common standard.

There is, however, a process for obtaining a measurement of one element in the energy of light capable of greater accuracy of observation than the photographic one. This also is chemical.

In the lecture on the energy of affinity a brief time was devoted to the peculiar manifestation of affinities under the conditions of the nascent state.

It is apparently a deviation from this form of energy when the two well-known gases, chlorine and hydrogen, are produced and intimately mixed, either in their nascent state or afterwards, in the dark or in the presence of that portion of the solar beam we call red. Under these conditions no rapid union of the gases takes place. Permit the evolution or the mixing of the two gases to be in ordinary light, properly so-called, and an intimate union, or rather an actual chemical combination, is a consequence.

If these gases be separately produced and collected in a glass vessel in equal parts, the union and formation of a new chemical compound in this glass vessel follows from exposure to light. If the light, or rather that particular portion of the solar beam to which chemical action is generally attributed, be permitted to act upon the two mixed gases, then the union takes place at a rate determined by the energy of some one or more of these constituent elements of light on which the combination depends. Where in the solar beam these constituents are is a question easily solved.

Every ray, or every portion of a beam of light, is capable of producing union between hydrogen and chlorine; but the combination takes place at very different rates, according to the portion of the beam which acts upon the united gases. The actinic portion will act seven hundred times as rapidly as the heat portion. That is to say, a certain combination will take place under the influence of this portion in one minute, which it will take more than eleven hours to accomplish under the influence of the heat portion. Therefore, by separating the ray of light, we can graduate the rate at which the combination occurs. Here are some glass bulbs containing chlorine and hydrogen which have never yet been exposed to the light. If one of these be placed under this globe of red glass, then the light that passes through it will be the portion of light corresponding to the heat end of the spectrum, and it will take hours to accomplish the perfect union of these two gases. If, however, one be placed under a globe of a blue colour, the light falling upon it will represent that belonging to the actinic portion of the spectrum, and the

gases will unite (if the experiment be successful), and explode in about ten seconds.

Whilst recognising this test and measuring gauge of the chemical brightness of certain lights, it must be borne in mind that it is chemical action, and not the energy, of light, properly so-called, that is measured. For instance, when the brightness of the sun's disc, as a case of light-brightness, is 520 times that of magnesium wire, the chemical brightness has been found to be not forty times as great.

Here are diagrams of two spectra, one of which is obtained from flint-glass. Now, flint-glass produces an effect which is considered to be due more to the physical property of density than to the elements of which it is chemically formed. Assume this diagram to be a faithful reproduction of the spectrum from flint-glass. Now, however similar another glass may be in appearance, yet if it differ in density and constituent elements the distances between certain lines in the spectrum may in some portions be the same, but in others they will differ. If, therefore, light be estimated from the spectral appearance of it after it has passed through any substance, it is clearly subject to the influence of that substance. Again, on another diagram is a series of colours produced by a process called diffraction. This is the apparatus, and this is the mode of producing those colours. At the object-glass end of the telescope there are a number of very fine lines drawn, and if the telescope be directed to a very intense speck of light, such as the reflected sun from a small silvered globe or the bulb of a thermometer, coloured bands are seen, containing the same colours that the flint glass spectrum shows. But the colours seen under this diffraction arrangement are very different in quantity to those seen under any other arrangement. A diffraction experiment is easily made by each for himself. From that hook a bright reflecting silvered glass globe is suspended, and two or three smaller ones of the same kind. If anyone is tired of listening, and feels disposed to go to sleep, they can perform this experiment very easily. Just close your eyes and allow the eyelash to interfere with that speck of light reflected from the globe, and you will probably see colours radiating on both sides. Those are colours due to diffraction, and there are modes by which they can be made to appear much wider apart than by the one now described. Taking the diffraction spectrum, we find that these distances, from D to E, say of the yellow portion of the spectrum, are not of the same length as the corresponding portion in the flint glass spectrum, and the same with the other portions, so that the proportions are quite altered. This is called the "irrationality" of the spectrum. Line D there becomes the middle of the spectrum instead of being, as it is here, very near to one end. The consequence is, when we talk of there being no heat in this portion of the spectrum, we have really and truly distributed the heat which ought to be condensed in F, G, over that large space, and therefore it shows on a fixed area much less heat than it would do not so distributed. If, now, these apparently unequal halves of the spectrum be examined for heat, it will be found that collecting them into two separate foci, the heat in the one focus is equal to that in the other. Clearly, had these portions been examined over equal areas the heats would not have been equal. Therefore the notion generally entertained of heat being confined solely to one end of the spectrum is not strictly true. That diffraction spectrum explains it, and there are other matters bearing upon it which, if time permit, shall be referred to presently.

That kinetic energy, of a character as important as any found in the other imponderables, exists in light, may be inferred from the fact that, if light be extinguished by falling upon such a surface as lamp-black, the stoppage of the ray—the consequent absorption of it—produces heat. The motion of the light has been converted into a motion called heat. If, however, the light be stopped by some of the salts of silver, then this

* *Journal of the Royal Institution for 1802, p. 170.*

motion is converted into chemical changes. The heat and the change are consequences of an energy in light. Nor is it only when influencing different substances that light effects different results. Take, for example, carbon, and note how varied is its behaviour towards light and electricity. When in the form of a diamond, then carbon transmits light and stops electricity; but when in the form of coke, into which the diamond is transformed by heat, then carbon transmits electricity, but stops light. No cause has yet been assigned to that which seems almost universally the case, viz., transparent bodies stop electricity—carbon, the metals and opaque bodies, stop light.

It is a popular opinion that sunlight or sun-brightness extinguishes household fires. May not this be from some hitherto undiscovered energy of solar light, for it is not the heat of the solar beam which thus causes the carbonaceous fuel in our grates to become dim? If the energy of light is to be studied, and its value to be estimated and brought within our powers of utilisation, it must be done through agencies widely different from those hitherto named. Looking at the order of creation, and watching the behaviour both of the animal and vegetable kingdoms, it seems that through them must be had our knowledge. Allusion has been already made to these. It may be well to investigate more closely the relation of the energy of light to them. No mode of measuring the energy of light in relation to animal life has been suggested, and yet its energy in this respect is more strikingly extraordinary than that of the other imponderables. Take one illustration only. When you knock at the door of a friend's bedroom, and receive no answer, how loud, and louder still, becomes the rap ere he awakes. How often are stories told at the breakfast-table of night noises unheard and unheeded by those asleep. Let but a beam of sun-light, or even candle-light, shine on the closed eyelid, and by some mysterious energy on the well-covered retina the sleeper awakes.

The worlds of animal and vegetable life awake and work mainly in consequence of some such hitherto unmeasured energy of light as that now alluded to.

Turn to vegetable life. With respect to this, Professor Helmholtz remarks:—"Take a seed, then look at the tree, and consider from what source has been derived all the material of the tree. Burn the seed, burn the tree, whence comes the different amounts of heat? Chemistry tells us that the heat is produced from carbon, oxygen, and hydrogen; these are derived from carbonic acid and water. Plants cannot obtain these except under the influence of solar light."

After plants have utilised the light it is not useable again for the same purpose. Take two screens of dark paper, such as these, with holes in them—say half an inch in diameter—one hole covered with letter-paper, the other covered with a green leaf; put pieces of photographic paper behind them, and expose to day-light or magnesium light. Beneath the letter-paper is a dark spot—an image of the hole; beneath the leaf is no discolouration. The leaf has utilised the light, the letter paper has not. The energy of that which passes through the leaf is spent, of that passing through the paper is not spent.

Although in plants a variety of operations take place, which must in some way unknown to us store up a large amount of energy, and although there is to all practical purposes no heat developed, yet we know well that there are thus stored up chemical tensions which give out their true physical value in heat and mechanical work, as the tissues of the plants are destroyed by a process of animal or other combustion. We are as yet quite at a loss to know how the plants do this, or by what elements in light, properly so called, it can be so completely and perfectly done.

Sir John F. W. Herschel, in a paper in the *Philosophical Transactions* for 1842, gives a most interesting account of

* Helmholtz, *Medical Times*, 30th April, 1864, p. 473.

an extended series of experiments on the action of the solar spectrum on vegetable colours. He operated upon the juices of the leaves, and also upon some of the resinous compounds of plants, and his conclusions have since been confirmed, viz., the action of the solar spectrum is confined to the visible region of it. The chemical or actinic rays act with chief energy upon silver or inorganic compounds, but are, for the most part, powerless upon vegetable colours: so also are the heat rays, or those below the extreme red. Thus Sir J. Herschel, in 1842, separated by a very broad line the luminous portion of the solar beam from the other parts of it. That the energy of the luminous portion of the solar beam is requisite ere plants can exercise their vital functions is well known to all who have made any of the experiments which show the extent to which, under the influence of that energy, plants can effect chemical changes. These changes take place most abundantly in the yellow, or in what our eyes would call the brightest, portion of the spectrum.

The energy of this luminous portion may be gathered from experiments made during the last few years by an American. Flowering plants were placed in different colours of the spectrum, and it was soon observed that their action upon carbonic acid gas depended upon the colour of the spectrum. He took a flower, and under the action of a red ray he did not get 1 cubic inch of gas off, but only 0.33 of an inch. As soon as he submitted that same plant to the orange ray, he got 20 cubic inches, and from the yellow he got 36 inches. But when the same plant was put under green, blue, indigo, or violet, he could not get the plants to act at all in the purification of carbonic acid gas, thereby showing pretty clearly the energy of light in the luminous portion of the spectrum as regards growing plants.

The decomposition, then, of the carbonic acid is effected chiefly by the energy resident in what may be called the yellow rays. It is a somewhat noteworthy coincidence, that the eye generally fixes upon the yellow portion of the spectrum as that possessed of the greatest brilliancy; it is also noteworthy that the spectroscopic reveals that in the atmosphere (viz., sodium) which, on being burnt, always produces a yellow band. It is, to say the least, curious that we cannot get heat by combustion in the air without the production of this yellow light.

It seems, then, that plants and human eyes are most sensitive to the same portion of the solar beam, and this portion is in light properly so called. May it not be that yellow light is most acceptable to the plant, and most impressive upon us, because carbon is in both cases involved—the retina of the eye being a carbonaceous compound? Had the retina been a salt of silver, then the greatest brilliancy would perhaps have seemed to be in the blue rays.

This identity in composition between the plant and that part of the animal on which light exercises its chief energy, suggests that in the influence of light on plants (whatever that may be) must be sought the data from which to deduce a mechanical rather than a chemical measure of the energy of true light.

The contrast of this energy in its effect upon the metal salts and plants is especially marked as regards time. On the metal salts it may be said to be instantaneous, but on the gums and resins of plants exposure for days and months to clear sunshine is needed to produce any marked action. A patient watching and building up on such scant data as may hitherto have accumulated will some day produce the dynamical equivalent of light.

There is one experiment here which will probably bear out what has been said. You are probably aware that plants, by receiving light, manufacture what we name colour. They manufacture the green material out of which the leaves and the general character of the plant is formed, and that green material is called "chlorophyll." This vessel consists of two beakers with the bottoms cut off, one about an inch and a

half larger than the other. The glass cylinders then left are fixed with marine glue in a wooden ring. The space between them is filled with a solution of chlorophyll, obtained by steeping for forty-eight hours common parsley in any cheap spirit, such as methylated alcohol, and then filtering. It therefore contains the green colouring matter of leaves. This green colouring matter has been made almost exclusively by the yellow portion of light, and not at all by the chemical portion, and, with a view to show this, we must refer to the spectroscopic view, namely, that chlorophyll, being really manufactured by yellow light, is practically saturated with yellow, and can take up no more. Thus, if a vessel containing a saturated solution of salt had a piece of salt dropped into it, that piece would not dissolve. If, now, there be placed inside this chlorophyll solution anything that produces these other coloured rays, we shall probably find that, while sensitive to the one colour, the solution will not be to the other. Here is some lithium, which shall be placed on a little piece of platinum wire and burnt, so causing a beautiful red flame. On putting the flame within the hollow cylinder containing the chlorophyll, you will see the yellow beam alone can pass through the green solution. The green solution having been made with that yellow beam, is thoroughly saturated with it, and can take up no more, but it can take up the other coloured rays, and therefore they do not pass through. In that portion of the flame rising above the green solution you see the red-coloured flame. Thus the yellow colour is consequent upon the saturated solution of chlorophyll, and therefore nothing but yellow can come through. The absorption of this yellow portion of the solar spectrum, by the vital energy of the plant and utilising the same in its composition, might have been inferentially suspected from the fact that leaves become yellow in the autumn, thus restoring in their death what, for want of a better term, we must call "the colour" they had absorbed in their life. The yellow colouring matter of the autumnal leaf is called "xanthophyll." Probably, as "chlorophyll" and "xanthophyll" are more examined and known, so the energy of light may be more appreciated and measured.

This examination of light, properly so-called, has led to another contribution towards an estimate of the energy. That plants grown in the dark are drawn to any crevice through which light enters has long been known. But it has not been so often observed that young plants bend the stems to the indigo portion of the spectrum, *i.e.*, if grown in red, or yellow, or green, they bend in one direction, but if in the violet, then in another direction. They recover the vertical position in darkness. May it not be that the energy in the indigo of the sky produces the vertical character of stem?

Thus light proper produces motion, and so assimilates itself to heat and electricity. The complementary colours of red and green (see the chromatic circle of Newton on diagram) are those which represent the relation of colour between the animal and vegetable kingdom. Plants reject green and absorb its complementary (red). The blood of animals is red, therefore animals should have green supplied in the fields and in our furniture.

That this energy of light is utilised in vegetation, and that practically we recognise it, may be noted in the ingenious modes by which in our small gardens we try to imitate nature. The nailing of branches on walls—an advance on this in espaliers on lattice woodwork, and the still more recent practice of cutting out the inner branches of orchard apple trees; also training others to hang in umbrella fashion, or the splaying of gooseberry bushes as funnels, all these are devices to permit of the more universal exercise of this unmeasured energy of light.

Light influences the colour of animals and the plumage of birds in tropical climates. In the arctic regions polar bears are white, like vegetables grown out of the influence of light—arctic foxes are white in winter and brown in summer. Fishes inhabiting deep water chiefly are

grey, or brown, or black; those living near the surface are of rich and various colours.

That the measurement of the energy of true light should be by an appeal to its influence on organised matter, and not on inorganic, is a testimony borne by all observations, and even suggested by the records of Creation, the earth having been prepared by the creation of light for animal and vegetable life even before they were formed upon it. This measurement has not yet been made.

(To be continued.)

CORRESPONDENCE.

THE CHEMICAL SOCIETY'S NEW ROOMS.

To the Editor of the Chemical News.

SIR,—Your correspondent "Ventilator" has given expression to the general feeling of dissatisfaction with which the *habitués* of the Chemical Society view its new meeting-room. The room in itself is well enough, but the way in which it is lighted and fitted is a disgrace.

Chemists are credited with a knowledge of the principles of sanitary science, and it seems incomprehensible why these should be so violated in the room over which chemists have control.

The trooper who, on the march to Coomassée, experiences an attack of sun-stroke will be cared for by a grateful country. But what will the grateful country think of the votary of Science who experiences an attack of gas-stroke at Burlington House, especially when she hears the victim is a chemist, and it has occurred in the chemists' special quarters.

I write more in the interest of Fellows non-resident in London, who are not quite up to the doings of their metropolitan brethren, and strongly advise all such who contemplate visiting their meeting-room in Burlington House to bring a flask of cold water, a slaked lime respirator, and an umbrella.—I am, &c.,

SLAKED LIME.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 10, 1873.

Action of Lead upon Water.—M. Dumas.—The author describes a former experiment in which five bottles containing leaden shot were partially filled with the following waters respectively:—Distilled water, rain-water, Seine water, Ourcq water, and well-water. It was found that the one containing distilled water showed in a very short time traces of lead in solution, whilst the waters charged more or less with calcareous salts contained none. The rapidity with which pure water acts upon lead is surprising, and the effect produced by traces of lime in preventing this reaction is not less so. It is impossible not to be reminded of Schloësing's observations upon clay, which, in pure water, remains indefinitely suspended, but which is precipitated by the slightest trace of lime salts.

The author thinks that pure water is an agent not yet perfectly known, and that its properties differ from those of common water more than is suspected. In the conversation which followed, M. Elie de Beaumont remarked that Schloesing's observation explained fully the clear and sparkling character of calcareous waters.

Absorption of Ammonia by Saline Solutions.—F. M. Raoult.—Among the saline solutions reputed indecomposable by ammonia, there are some which, as they are saturated with this gas, lose the faculty of holding in solution all the dissolved salt, and deposit it in the form of crystals, which may, or may not, contain ammonia. There are others which, although concentrated, deposit nothing under these circumstances; the experiments of the author refer to the latter. The results show that the solubility of ammonia in solutions of potassa is less than in pure water, in proportion as such solutions are more concentrated. Solutions of soda act exactly like those of potassa of the same strength. Solutions of nitrates of soda and of ammonia absorb just as much ammonia as pure water under the same circumstances. Dry nitrate of soda absorbs not a trace of ammonia, while nitrate of ammonia takes up a considerable quantity. Solutions of nitrate of lime absorb more ammonia than does water, though there is no evidence either of decomposition or of combination. As to the effect of the degree of concentration of solutions upon the quantity of ammonia absorbed, the author proposes the following law:—The difference between the coefficient of the solubility of ammonia in water, and in solutions more or less concentrated of one and the same salt, is proportional to the weight of salt contained in a constant volume of the liquid, measured before the absorption of the gas. This law may meet with exceptions for the extremely concentrated solutions of some bodies, such as the hydrates of potassa and soda, but it holds good for all whose boiling-points do not exceed 110°C .

Presence and Determination of Titanium and Vanadium in the Basalts of the Neighbourhood of Clermont-Ferrand.—M. V. Roussel.—The author finds the above basalts richer in titanium than any hitherto examined. The samples, in fine powder, were fused with thrice their weight of carbonate of soda; the mass, when cold, was powdered, and treated with water acidulated with hydrochloric acid; it is evaporated to dryness, heated for twenty-four hours on the water-bath, treated anew with acidulated water, and then filtered. The silica eliminated is, after calcination, set to digest for twelve to eighteen hours in hot concentrated sulphuric acid, treated after cooling with an excess of cold water, and filtered. This operation is repeated, and the total liquid is mixed with ammonia, which throws down titanic acid. It is filtered, washed, and ignited. The liquid separated from the silica contains also titanic acid; to separate it, it is treated with sulphate of soda, sulphurous acid, and hyposulphite of soda, boiled for twenty minutes, and there is left the mixed precipitate of sulphur, alumina, and titanic acid. The sulphur is driven off by gentle heating, and the residue is mixed with the former precipitate, and digested in a sealed tube with pure, hot, concentrated hydrochloric acid, in order to eliminate the alumina. After this series of operations, the titanic acid is pure, and may be dried and weighed. The same basalts contain vanadium, but in a far smaller proportion. To obtain a ponderable quantity, it is necessary to operate upon a sample twenty times larger than is required for the detection of titanium. The basalt is melted with carbonate of soda, and the mass oxidised with a little saltpetre. After cooling, the pulverised mass is treated with a large quantity of boiling water, filtered, and washed perfectly. The liquid is evaporated, boiled with carbonate of ammonia, and filtered, treated with hydrosulphate of ammonia, and left to settle for two or three days. If the solution contains vanadium, at this moment the fine red colour of sulphide of vanadium when dissolved in an alkaline sul-

phide appears in the liquid. It is filtered, and hydrochloric acid is poured into the liquid, which throws down sulphide of vanadium mixed with sulphur. The latter disappears on careful heating, when the sulphide of vanadium, VS_2 , is weighed. The largest percentage of titanium was 2.378, and that of vanadium 0.023.

Determination of Sugar by means of Iron.—E. Riffard.—This method has been already noticed in the CHEMICAL NEWS.

Examination of Law Proposed by M. Helmholtz to Represent the Action of Two Elements of a Current.—M. Bertrand.

Action of Water on Lead Pipes.—M. Belgrand.—This note goes to prove the innocuity of lead pipes in the Paris water service. Of the public pipes, there are only 3000 m. of lead out of a total of some 1,400,000 m. The branch pipes for domestic use have a total length of 1,580,000 m., but in this network each litre of water traverses only from 5 m. to 100 m. of lead, and, where the house is inhabited, the water is but a short time in contact with the lead—nine hours at the most (in the night). In the 3 kilometres of public pipes, the interior surface is quite smooth, and without trace of erosion, even in pipes 200 years old. The branch pipes have a thin adherent crust (lime, &c.), which hinders the contact of water and lead. M. Belgrand further made a series of analyses of water used in dwelling-houses, and found no traces of lead. His collaborateur, M. Le Blanc, experimented on a longer contact of water with lead; and his tables show that very pure water, such as that from the wells of Grenelle, though possessing much less saline matter than the Seine water, has yet the property of preserving lead from oxidation during long contact. Rain-water, even, does not attack the lead, unless it has been received after a sort of prolonged washing of the atmosphere by rains. When it is become insensible to the action of reagents of lime, it begins to attack the lead rapidly, like distilled water. Salts of lime, in the most minute quantity, notably prevent the oxidation of lead in contact with water. The general conclusion M. Belgrand arrives at is that the danger in Paris is *nil*, and that it is not desirable to substitute other pipes for the lead.

Historic Point Relative to Animal Heat.—M. Berthelot.—The point is, that M. de Lagrange was right in supposing, in opposition to Lavoisier, that animal heat was not wholly produced in the lungs, but wrong in his grounds for this view, which were that the organ would in that case have been in danger of destruction.

Establishment of a Meteorological Observatory at the Foot of the Pic du Midi by the Ramond Society.—M. Deville.

Note on Magnetism.—M. Gauguain.—The author, starting from an observation by M. Haecker, experimented on the changes in a horse-shoe electro-magnet when its armature is detached. A current was passed, the armature applied, then detached, then the current broken, and the armature applied and removed several times successively. The decrease of magnetism was measured by the author's method of induction currents, and these currents of demagnetisation were, for the first, second, third, fourth, and twentieth separation successively, 176.0, 19.5, 16.0, 14.5, and 13.4. When the armature has been applied and detached twenty times, the magnetism is not varied, though the process be repeated ever so often; and if the magnet be then put aside, with or without its armature, it will be found after some months in the same state as when left. Thus, in speaking of the magnetism acquired by iron in different conditions, it is necessary to mention the number of separations of the armature after the source of magnetisation has been suppressed. There are circumstances (M. Gauguain proceeds to point out) in which the separation of the armature seems to increase the magnetisation. Having brought an electro-magnet to the above constant state (Haecker), he determined the curren-

of detachment (*d'arrachement*) developed by this constant magnetism. The series of operations indicated having been repeated fifty times, he found the value of the current at the end of each series increase as the operations were multiplied, at least to a certain limit. It rises to the extent of a fifth of the value obtained at the end of the first series. This increase does not depend on the time during which the reducing current circulates; it is the same when this passes for an hour and for only a few seconds. The increase does not occur when one interrupts and renews the inducing current a number of times without detaching the armature. The armature must be detached after each of the interruptions of the inducing current. It might thus appear that the detachment of the armature increases the magnetisation, but this the author does not consider a true interpretation of the facts.

Aqueous Exhalation of Plants in Air and in Carbonic Acid.—M. Barthelemy.—The author experimented by an improved form of Mariotte's method, placing a branch in a closed receiver, and measuring the water condensed. He considers the aqueous exhalation may occur in three ways—(1) By insensible exhalation over the whole cuticular surface, through a veritable gaseous dialysis; (2) by a sudden emission of saturated gases, which escape by the stomata when the plant is subjected to a rapid elevation of temperature (especially in a receiver); (3) by accidental exudation, arising from deficient equilibrium between the absorbent action of the roots and the work of the aerial parts, and fixation of carbon added to the elements of water, a work which ceases with the light. He further concludes that heat exercises a great influence on this function, and that, with equal temperature, carbonic acid in presence of light, has the effect of diminishing the evaporation.

New Researches on the Upward Passage of Nutritious Matters in Bark.—M. Faivre.—(Extract).—The experiments consisted in making annulations, partial or complete, on the stems and branches of mulberries, walnuts, and cherry-laurels; also valves or tubes of bark separated from the wood and bearing buds; and in combining complete annulations with partial, or with valves or cortical tubes. Direct evidence was obtained of the ascent by the bark.

Influence of Drinking-Water in the Propagation of Cholera.—M. Colin.

Several Cases of Intermittence of the Voltaic Current.—M. Cazin.—The first experiment was briefly this—A coil, connected with a battery, passed round an iron tube; the circuit could be opened or closed by a platinum point, which dipped in mercury. If, the platinum and mercury being first separate, they were put in communication with the armature of a condenser, or if a layer of alcohol was interposed between the mercury and the platinum point, a continuous sound was heard in the iron core (it ceased if the alcohol was suppressed or the point dipped in the mercury); this indicates that the current passed through the glass in the former case, through the alcohol in the latter, and that its passage was intermittent. The iron core undergoes a rapid series of magnetisations and demagnetisations. The author thinks the cause of the intermittence is the condensing action of glass and of alcohol. When the two faces of the insulating substance have acquired a certain electric potential, a discharge takes place through the insulating layer. The magnetism of the core grows during the charge of the condenser, and diminishes during its discharge. The sound is produced during the diminution of magnetism. The second experiment refers to the spark of rupture, which, produced in alcohol in the above arrangement, is observed to be compound, and the sound it gives prevents a similar mode of division. The production of a sound in the condenser also proves that there is a partial discharge through the insulating matter, although this appears nowhere to be perforated. In a third experiment, the platinum point could be moved up and down in its support by screwing.

Dipping in the mercury, it is gradually raised till the spark passes through the alcohol; then a succession of sparks occur, and continues some time. The surface of mercury evidently oscillates under the point. One possible cause of this is that, the spark being formed by mercury vapour, the elastic force of this vapour depresses the surface of liquid. The latter returns to its original level, passes it in virtue of acquired velocity, and rejoins the platinum point; falling back, it produces a new interruption, and so on. But this cannot be the only cause, for the circumstances favourable to this automatic interruption are those which accompany the decomposition of the spark of rupture into a small number of bright successive lines. By changing the extent of the condenser, one may change the number of divisions in the spark; if the condenser be suppressed, there will merely be a crepitating voltaic arc. Probably the period of oscillation of the mercury and the intermittence of discharge of the condenser are in mutual dependence. The crepitations of the ordinary voltaic arc are, the author thinks, a phenomenon belonging to the class above indicated. All the facts permit of being united by the following proposition:—The interposition of a suitable resistance in the voltaic circuit causes intermittence of current. Further, the important conclusion is warranted that the current is a succession of modifications which are accomplished periodically in the circuit.

Process of Determining the Nodes in a Sounding-Pipe.—M. Bourbouze.—The author substitutes, for M. König's capsules, a simple membrane of flexible caoutchouc, to which he attaches a light silvered mirror, which oscillates with it. A ray of light is reflected from the mirror, and figures like those of M. Lissajou's are obtained. The image has its maximum of elongation when the mirror is at a node.

Action of Aërated Water on Lead, considered with reference to Hygiene and Legal Medicine.—M. Fordos.—The author's remarks are partly directed against the employment of lead in rinsing bottles.

Influence exercised by the Moon on Meteorological Phenomena.—M. Marchaud.—From examining the distribution of storms in the country between Paris and La Manche, from 1785 to 1872, M. Marchaud finds an appreciable relation to the age of the moon. Thus the probabilities of appearance of storm phenomena are great the tenth, fourteenth, and fifteenth days of the moon—especially the tenth; they are appreciable upon the eighteenth; well marked at the twenty-first; decrease from the twenty-second, and again become very important in the three days which precede or which follow the neomenia. On the other hand, the probabilities descend to their minimum on the twentieth and twenty-fourth day, but above all the sixth. The author also shows, by tables, &c., that the moon has an appreciable influence on thermometric and barometric changes, on the state of the sky, and the distribution of rains.

Processes for Determining the Direction and Force of the Wind, Suppression of Vanes, Application to Cyclones.—M. Tany.—Vanes have three faults:—(1). They indicate a direction when there is no wind. (2). They do not indicate the force or velocity of wind. (3). They only show the horizontal component, not the real direction. The author substitutes a light resistant bandrol, or little flag, suspended by a cord from a metallic ring, pulleyed on a vertical rod.

Bulletin de la Societe Chimique de Paris, tome xx., Nos. 8 and 9, November 5, 1873.

Assay of Plumbiferous Mammals.—J. Loewe.—In treating lead ores with nitric acid, a loss generally results from the formation of insoluble sulphate of lead. The solubility of this salt in hyposulphite of soda renders it possible to avoid this inconvenience. After treatment with nitric acid the residue is exhausted with boiling

water, until the soluble salts and the acid are completely eliminated. It is then digested in the cold with a concentrated solution of hyposulphite. After this treatment has been twice or thrice repeated, the residue is exhausted again with water; the lead is then precipitated from the filtrate by sulphuretted hydrogen or sulphide of ammonium: to facilitate the agglomeration of the precipitate and its washing, it is heated in the water-bath. The sulphide is then converted into sulphate, and its weight added to that of the sulphate obtained directly.

Separation of Uronic Oxide and Phosphoric Acid.—E. Reichardt.—This separation can be effected by dissolving the phosphate of uranium in carbonate of soda, and precipitating with a salt of magnesia. If the precipitate of phosphate of uranium is old, it is necessary to dissolve it first in hot concentrated hydrochloric acid, adding nitric acid to peroxidise any iron present. The solution is then heated, and soda added in excess. After a new filtration the phosphoric acid is thrown down by adding ammonia and chloride of magnesia. After twenty-four hours, the liquid is separated from the ammoniacophosphate of magnesia. It is acidified with hydrochloric acid, heated, and the oxide of uranium precipitated by ammonia, avoiding excess.

Separation of Molybdic Acid from Phosphoric Acid.—E. Reichardt.—This separation is effected in a manner analogous to the former. The phospho-molybdic compound is dissolved in carbonate of soda, and heated to boiling. After having precipitated the phosphoric acid by means of magnesia-mixture, the solution is treated with *aqua-regia*, and evaporated to dryness to expel excess of acid. The residue is then treated with water, which leaves the molybdic acid undissolved.

On Certain Derivatives of Cyanoxycarbonic Ether.—A. Weddige.—Alcoholic ammonia acts upon cyanoxycarbonic ether, yielding a well-crystallised body, which the author had regarded as the corresponding amid. A new examination convinced him that in this case cyanide of ammonium and urethan were formed. Aniline acts in an analogous manner, and yields hydrocyanic acid and carboxanilidic ether. Methylamin appears to act in a similar manner. Hydrochloric acid decomposes cyanoxycarbonic ether, slowly in the cold, producing oxalic acid and an ammoniacal salt. If sulphuretted hydrogen is passed into the alcoholic solution of this ether, yellow crystals are separated, which crystallise from common ether in fine lemon-coloured prisms, and from boiling water in fine yellow needles. This compound fuses at 63° to 64°. Sodium yields, with cyanoxycarbonic ether, brown, viscid products. If left in contact with an equivalent of bromine, moisture being excluded, this ether yields, after the lapse of two days, long needles, which are obtained in greater quantity if the mixture is heated in a sealed tube to 100° to 110°. After crystallisation from boiling alcohol, this body forms small, white, hard prisms, fusible at 164° to 165°, and very sparingly soluble in water and ether. They form a polymer of cyanoxycarbonic ether. Boiling alkalis decompose these crystals, yielding ammonia and oxalic acid.

On α -Cresyl-disulphurous Acid, and on some of its Derivatives.—P. Håkansson.—By the action of fuming sulphuric acid upon cresyl-sulphurous acid, the author has obtained two cresyl-disulphurous acids, α and β . He considers the acid α isomeric with the cresyl-disulphurous acid obtained by Senhofer. The author has examined its potassium, sodium, ammonium, barium, calcium, magnesium, aluminium, manganese, cobalt, cadmium, nickel, zinc, lead, copper, and silver salts, its chloride and amid, the disulphhydrate of tolylen, and disulphobenzoic acid, with some of its salts.

Modification of Nutrition after Loss of Blood.—M. Bauer.—A physiological paper.

Chemical Study on Fever.—M. Manassein.—The author shows that during fever the digestive power of the

gastric juice is very slight, but increases on the addition of an acid.

Case of Poisoning by Arseniuretted Hydrogen.—M. Troost.—Arseniferous zinc, used in separating silver from lead at Stolberg, proved fatal to three of the workmen. Arsenic was detected in the viscera and the fluids of the bodies.

Detection of Metals in the Organism.—MM. Mayençon and Bergeret.—The tissue is treated with *aqua regia*, and a galvanic couple, consisting of an iron and a platinum wire, is plunged in the liquid. After thirty minutes, the couple is withdrawn, washed in distilled water, dried, immersed in chlorine gas, shaken in the air to get rid of the chlorine, and the platinum is finally rubbed with paper soaked in a solution containing $\frac{1}{100}$ th of iodide of potassium. Mercury produced a red, and lead a yellow, colouration, &c.

PATENTS.

ABRIDGMENTS OF PROVISIONAL AND COMPLETE SPECIFICATIONS.

Improvements in the manufacture of glass mirrors, and in apparatus or grinding and polishing plate glass, also in engraving on glass. Thomas Brown, 96, Newgate Street, London. (A communication from Edouard Dodé, Paris.) March 5, 1873.—No. 802. This Provisional Specification describes apparatus for grinding and polishing plate glass, also coating rough glass with a platina enamel, and subsequently platinising such enamel; also engraving or ornamenting glass by the use of boracic acid applied to the surface of the glass in any desired pattern, the glass being afterwards submitted to sufficient heat to fuse the acid.

Improvements in the treatment of blood for the manufacture of manure. Leonce Oscar Durruthy, and Henri Prosper Lissagaray, both of No. 20, Rue des Petits Hôtels, Paris. March 6, 1873.—No. 800. This invention consists in treating blood with hydrochloric, nitric, sulphuric, sulphurous, or other mineral acids, or with sulphites, especially sulphite of soda.

Improvements in drying and roasting malt, grain, and other substances. George Phillips, 71, Tufnell Park Road, Islington, Middlesex. March 6, 1873.—No. 821. This Provisional Specification describes special means of applying hot air under pressure for drying and roasting malt, grain, and other substances.

Improvements in apparatus employed in the concentration of sulphuric acid. Henry Bernoulli Barlow, patent agent, Manchester, Lancaster. (A communication from Nicolas Joseph Galland, engineer, Paris.) March 7, 1873.—No. 827. This invention consists first in the mode of constructing the vessels in which the sulphuric acid is concentrated, and secondly to the general arrangement of the concentrating vessels, the apparatus for agitating the acid, the manner of applying heat to the vessels and the pipes for connecting them together, and to the cisterns in which the vapours are condensed and the acid is collected, and the pump for forming a partial vacuum. The concentrating vessels are made of cast-iron, lined with lead or other suitable soft metal.

Improvements in the manufacture of sulphates of soda and of potassa, and in the production of chlorine. James Hargreaves, chemist, and Thomas Robinson, iron founder, both of Widnes, Lancaster. March 7, 1873.—No. 828. The patentees avail themselves of the same reactions which occur in roasting cupreous pyrites with common salt preparatory to separating copper by the well known wet process, but they keep their chlorides free from contact with large masses of oxide of iron. Copper, or a salt thereof, is added to chloride of sodium or potassium, and the mixed mass exposed to the action of sulphurous acid gas and atmospheric air. The chloride is converted into sulphate, and chlorine set free. The chlorides may be moulded or broken into suitable pieces. Manganese or chromium may be used instead of copper. The means and apparatus preferred are described in previous patents, Nos. 3045, 3047 (1870); 1733, 1854, 1920 (1871); and 3052 (1872).

A new or improved amalgam for the better imitation of silver. John Keene, Scott's Yard, Bush Lane, Cannon Street, London. (A communication from Madame Pirch Baudvin, Rue des Marais, Paris.) March 8, 1873.—No. 834. The novelty in this case consists in the peculiar selection of metals and their relative quantities, especially the introduction of cobalt, to form an amalgam resembling silver.

Improvements in utilizing refuse matter for the manufacture of fuel and manure. James Wadsworth, machinist, Manchester. March 8, 1873.—No. 841. The features of novelty in this invention consist in taking street sweepings, ashes and cinders, coke from gas works, mud from sewage and foul river settling beds; and, when necessary, adding a portion of clay to give a proper consistency. I then mould the same into suitable shapes for burning as fuel, or I calcine in kilns or suitable furnaces. Or I sometimes take the street sweepings alone, or with the mud hereinbefore mentioned, and mix with a portion of clay and treat in like manner. The residue when burned as a fuel I crush to powder, and use as a deodoriser as described.

New utilisations of the acid residues resulting from the manufacture of chlorine. Frédéric Kuhlmann, Professor of Chemistry, Paris. March 8, 1873.—No. 847. The invention consists—(1) in the application of the residues of the manufacture of chlorine for the preparation

of Linexide of manganese, the protoxide of manganese being super-oxidised by means of ozonised air or preferably with nitric acid or nitrous gases. (2) In the application of the oxide of manganese precipitate, obtained by the action of lime on the residues of the manufacture of chlorine in metallurgy.

Improvements in the working of coal-gas tar. John Rowley, chemist, 84, Camberwell Road, Surrey. March 10, 1873.—No. 853. I take the coal-gas tar and its homologous products, either together or separate, and treat them with acids, alkalies, and chlorine. I then distil and obtain benzol, anthracen, and other products suitable for making aniline dyes.

Improvements relating to the manufacture of chlorine by means of compounds of manganese regenerated in the wet way. Walter Weldon, 29, The Cedars, Putney, Surrey. March 11, 1873.—No. 868. This invention relates to the process which is the subject of my former patents, dated respectively the 26th July, 1866; the 18th January, 1867; the 4th September, 1867; the 20th February, 1868; the 24th February, 1868, and the 10th March, 1869. It consists in economising manganese by subjecting the deposit which forms in the chloride of manganese settlers to a certain methodical washing; in economising acid and limestone by employing in the stills an excess of manganese mud, neutralising, if necessary, the last portions of the acid by lime, allowing the undissolved peroxide of manganese to settle out, and then, when it has accumulated sufficiently, employing the deposit so obtained instead of fresh manganese mud, and dissolving it completely by an excess of acid; and in certain arrangements of apparatus for effecting these objects.

NOTES AND QUERIES.

Fluorescent Spectrum.—Will some one kindly tell me what is meant by this?—WM. JOHN GREY.

Extraction of Lead from Sulphate.—Can any of your correspondents kindly inform me of a process for extracting lead from the sulphate arising in the manufacture of sulphuric acid?—C. H. N.

Glacial Acetic Acid and Aceton.—Will any of the readers of the CHEMICAL NEWS give the inquirer any information as to how the above articles are made?—R. W.

Fuller's Earth.—I understand Fuller's earth, in a powdered state, is extensively employed on the Continent for refining rosin oil. Can any of your readers inform me of the process, and where ground Fuller's earth may be had?—A. K. C.

Notes on the Utilisation of Sewage.—(From the "Report of the Main Drainage Committee for 1864," vol. 487).

2721. (To Mr. Whitehead). Does the lime process succeed in purifying the sewage?—Very far from it, and I take it that one cause is this: that the lime is not applied in the most effective manner. I think it is the same as the smoke-consuming furnaces; it depends upon the discretion of the man who puts on the coal whether it is effective or not.

2722. (To the same). Have you ever known lime to succeed in purifying the water?—I have known lime to succeed, but this evil attaches to it, that it kills the fish.

2723. And does it not also render the water unwholesome for drinking?—Quite so.

2724. Would it be unprofitable as a commercial speculation?—Certainly.

2725. You think that it would not be good for agricultural purposes?—No, as far as stock was concerned.

2726. Then would you say that the lime process was a failure?—I say that the lime process as it has been carried out in this instance was a great failure, but I think that it admits of great improvements.

2727. Previous to this lime process being used, the cattle drank the water of the stream, and now they cannot drink it and the fish die in the stream; is that so?—That is so.

LITERARY.

Messrs. Paterson & Vary are prepared to undertake the original composition of all kinds of Descriptive Bills, Pamphlets, Lectures for new ideas, Inventions, Exhibitions, or for Medical Purposes. Addresses, Debates, Sermons, Tracts, Biographies, Sketches, Essays, Tales, &c., prepared in an acceptable manner. Works revised for the press. Translations effected with fidelity and spirit. Births, Deaths, and Marriages searched for. Messrs. PATERSON & VARY, Literary Bureau and Agency, 2 King's Road, Bedford Row, London W.C.

Lecture Notes for Chemical Students. By EDWARD FRANKLAND, D.C.L., F.R.S., Professor of Chemistry in the Royal School of Mines, &c. Second Edition. Vol. I. (Inorganic), 4s. Vol. II. (Organic), 5s.

"These 'Notes' will, we believe, be found very useful for students, containing as they do exactly what is wanted, without being overloaded with any superfluous matter, and what is of no less importance in a constantly expanding science like chemistry, bringing up the information to the latest date, and in accordance with the most advanced views of English and continental chemists."—*Educational Times*.

London: JOHN VAN VOORST, 1, Paternoster Row.

Now Ready, Price 5s.

Milk-Analysis.—A Practical Treatise on the Examination of Milk (including Cream, Butter, and Cheese). By J. ALFRED WANKLYN, M.R.C.S., Corresponding Member of the Royal Bavarian Academy of Sciences, Public Analyst for Bucks. London: TRUBNER and CO., Ludgate Hill.

THE QUARTERLY JOURNAL OF SCIENCE.

Edited by WILLIAM CROOKES, F.R.S., &c.

On Friday next, No. XLI., January, 1874, price 5s.

CONTENTS.

Analysis of Food, Water, and Air.—Mr. WANKLYN has opened a Laboratory at 117, Charlotte Street, Fitzroy Square, and is prepared to give Practical Instruction in Chemical Analysis to Medical Officers of Health, and to persons proposing to undertake the duties of Public Analysts under the new Act.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Theoretical and Practical Chemistry.

Mr. SIDNEY W. RICH, Analytical and Consulting Chemist, undertakes all kinds of Analyses, including the Analysis of Water, of articles of Food and Drink, and of Commercial Articles.

Mr. RICH also undertakes Investigations relating to Patents, Manufactures, &c. Gentlemen who wish to carry out Investigations personally may have a separate room if privacy be needed.

PRACTICAL CLASSES commence in October, January, and March, but laboratory pupils who work independently may enter at any time.

Further Particulars may be obtained at the Laboratory, 1A, CHELSEA STREET, TOTTENHAM COURT ROAD, LONDON, W.C.

BERNERS COLLEGE OF CHEMISTRY.

EXPERIMENTAL MILITARY AND NAVAL SCIENCES under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.

Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.R.S. M.S.A., at the Institution.

MR. C. ESTCOURT, F.C.S.,
ANALYTICAL AND CONSULTING CHEMIST.

Commercial Analyses of all kinds performed.

BOROUGH LABORATORY,
8, St. James's Square, John Dalton Street
MANCHESTER.

THE CHEMICAL NEWS.

(Continued from p. 282).

I AM very glad that the two letters in last CHEMICAL NEWS are sufficiently calm to allow me, without feeling annoyed, to reply. I never expect very tolerant language from scientific men. I am, however, quite pleased with the words alluded to, in the sense that they seem the result of a desire to deal fairly in the matter, and to listen as well as to think. I cannot at present discuss, as I said, but I must make my meaning plainer, and do what honour my words can do to two men. The first of these is Leucippus (some people prefer Leukippos, for reasons of a limited range in the English language). I prefer to call the atomic theory of the ancients that of Leucippus, from the simple fact that he first propounded it. Many men took it up afterwards, and Lucretius went carefully into detail, but the first that published it deservedly takes the name, and I think this is too much forgotten. In modern times we have Newton, with exactly the same theory, but it would be unfair to connect him with it, because he really added nothing essential.

Dalton held the same theory of fundamental atoms or ultimate particles, as Dr. Wright has observed, and as I said in last letter; but he made an addition so decided that he marks the most important era in the history of atoms. Lucretius tells us that the primordial atoms are very different in their forms, so different that some are hooked. This shows an imperfect conception of the subject, because he did not see that smooth atoms could make all forms and qualities of bodies. Dalton had no more to add him upon physical grounds, and he explained his idea of atom or ultimate particle from the chemical action of bodies. He had the idea of mechanical fitting. This suited the thousands of chemical phenomena so well that it has altered the whole *cosmos* to our eyes, and our theories of the constitution of compounds have had reason in them since Dalton's time. He says that a certain volume enters into combination, and it has a certain weight. That is proved to be true, and it is his, without theory. In addition, he says that the certain weight is the ultimate particle, because you find it however low you go. That may be said to be theoretical, but it is full of good analogy and sound sense. Some like to use "equivalent," but that word does not mean anything by itself, and can stand only in relation to something else. If, for example, we have oxygen and calcium alone, neither can be called an equivalent. One may say, equivalent to what? But if sodium takes the place of calcium, then it may receive the name *pro tempore*. But what is the bulk of an atom? Dalton said, substantially, I do not know; but when you have found the smallest possible piece of calcium oxide, then it may be divided into an ultimate particle of calcium and one of oxygen. His meaning is clear enough, and the use of atom in the sense used hitherto by chemists is rationally founded, whilst the use of equivalent assumes virtually the same facts, but hesitates to give them their full bearing, according to my mind. Dalton having decided, proceeded to give the relative weight of each of his ultimate particles, and arranged the subject, putting aside many fancies of Lucretius, and back to Anaximander, with a few words.

Supposing Dalton to be correct in his very common-sense view, I think we ought to call the atom, when it has attained this precise state of definition, the Daltonian atom, because we really ought never to lose an opportunity of honouring those men who have been so divinely

gifted as by a thought to have illuminated all the times to come. It is as if they had a part of the power which said "Let there be light, and there was light." This of course is not used as argument,—nor indeed am I arguing at all but thinking that I am making matters clear.

Now although Dalton could say, proudly, "Show me, even in idea, a particle so small that it shall not conform to my rule," there is a certain faculty that leads us on to ask—What would happen if Dalton's atoms were split? We have no chemical experiment leading us to believe that this ever occurs amongst us, but I wish to say that a man may be a believer in Daltonian atoms, and yet believe that there are no final atoms; or he may believe in no matter existing at all. I fear I am repeating myself, but it may do no harm to let this be said in a fresh series of words. I dare say Dalton, as a far-seeing man, would have speculated as readily as any man on the divisibility of the elements, or "articles" as he sometimes called them, but he did not pretend to have gone farther.

Whilst the division of the Daltonian atom is one mode of, theoretically at least, obtaining new elements, there are other methods, and not the least beautiful; perhaps the most beautiful of all is that of the late Prof. Graham's. He gave it as a possibility that, there being one matter,—and we must suppose that to be atomic,—the differences of elementary bodies may be caused by the different rates of speed at which the atoms move; in other words, that atoms do not differ in shape, size, &c., but in primordial activity. This was the result of his examination of gases. It is a beautiful theory. We are of course obliged to give these atoms a primordial power, and this moderns agree to do along with the ancients. Even here, however, we must suppose a certain force capable of overcoming that primordial force, and, if so, the speed would be destroyed and a new element would come to our view. Who knows? perhaps it would be too active, and seek combination before we caught it; but with what would it combine? These are questions only, but they show another mode of supposing a chemistry beneath our chemistry; and our wandering exacting intellects demand that even that primordial atom, before deciding on its velocity, shall be divided, that we may see what it contains.

Another interesting view was put out by Sir William Thomson, indicating a variety of motions—not mere speed—in a primeval fluid or substance. In this case the practical Daltonian stage of matter would be a very complex body. Not having the paper before me I shall not attempt to say more; but the motion in these atoms, also, we may suppose overcomable by a superior motion, although he seemed not to think so.

In both of these latter cases, some adjustment would be requisite to fit into Dalton's weight, but still, even in them, it is needful to imagine a certain amount of matter gathered together to act. The reason of this is that we cannot picture to ourselves clearly what would be the condition of the matter before it was so gathered together. And, indeed, we become able to talk sensibly only when we begin from the atom upwards; below it is speculation. For this reason, a chemist may be a most confirmed atomist, and hold any theory of the constitution of matter. As to infinite divisibility, some have thought of it all their lives, and read much, but are glad to rest in the belief that they cannot understand why it should be true, or why it should not be true. None of the above oppose Dalton, only cause a change, which, with permission, may form the subject of a third letter. When we come to the physical theories of the present time, we find men proceeding with certainty, or almost certainty, in the belief that gases are composed of atoms. Now Dr. Wright would say that this is scarcely correct, because "molecule" is the word used. I know it, but I have given my own interpretation of the word atom, or, rather, that of chemists taking Dalton's view. I call one "the smallest undivided particle;" that of the older and of many later physicists is "the smallest indivisible particle." In considering the constitution of gases, our

physicists speak of the movement of undivided particles, that is, particles which they have no good reason to consider as existing divided in the gas. The molecular mobility of gases, or of elementary particles of gases, is not put a stop to by combination with another gas, as oxygen with nitrogen, and if we call one an atom, and the other a molecule, we should probably speak more according to our knowledge. Atom, used as an undivided molecule, suits chemists well, because they can say, as now, an atom of a compound substance, say albumen, knowing that in that case, although physically divisible into several elements, the removal of any one destroys the identity of that which can exist only as a group.

I have not opposed Dr. Wright by speaking against his view, but I may say that I see no weakening of the Daltonian atom in any theory of motion among the particles; Dalton's theory is wide enough to hold it all. When bodies are isomeric, we naturally look either to a difference in the arrangement of the particles, or a motion amongst them. Dalton's theory is well enough prepared for the first; I do not know that he thought of the second, but, had he done so, he would not have required to change either weight, number, or size of any of the component parts.

I shall only add that the quotation from Watts's magnificent and valuable "Dictionary" does not please me; and, first, the words "some use it in its strict Daltonian materialistic sense." In what other sense can we use it except a materialistic? Even Bosovich would use it in its materialistic sense. The immaterial, if it is desired, would certainly be something below the atom in any use of the word known to me. Again, "Others use it in an abstract sense, only to express the smallest indivisible combining proportion of a body." Why, that is Dalton's meaning leaving out the word abstract, which is not in harmony with the other clauses, so that he includes both. Then it is added, "and consider the proportional number of a body as an ultimate or unexplained property belonging to it." I feel sure that Dalton considered it both ultimate and unexplained. I do not understand *greatest common divisor* system, except in a sense which brings us also to Dalton's atom; his system is, in fact, so wide that I do not see any facts that shut it out, but I have tried to see, and, in doing so, the subject beyond has become a mystery. If, however, Dr. Wright really thinks that the use of the word atom confuses the student's mind, that certainly is a good reason for not using it, and better for a teacher than any facts which came from the beautiful researches of Joule, of Clausius, of Clerk-Maxwell, Sir William Thomson, and Graham. I think it better, however, before changing, for chemists to see what these researches will produce; to me they are developments of Dalton; but the subject in abstract is very difficult, and it will be long before we all think alike, so I give only a few scraps of the thoughts of one who can see but a little way at best, being only an

ATOM.

ON THE SENSITIVENESS OF BROMIDE OF SILVER TO THE SO-CALLED CHEMICALLY INACTIVE COLOURS.

By PHIL. HERMANN VOGEL.

It is known that certain colours—such as red, yellow, and green—act very slightly, or not at all, upon a photographic film. This circumstance not only puts a difficulty in the way of the photographer of colours (oil paintings, &c.), but is also a stumbling block to the portrait photographer, who has to depict not only coloured drapery, but yellowish complexions, blonde hair, and red cheeks. High lights which are tinged with yellow appear dark in photography, and shadows when tinged with blue are reproduced lighter

than they should be, the only way of subsequent retouching matters being by means of retouching upon the negative.

This abnormal sensitiveness for colours present in photographic plates is more conspicuous when the lines of the spectrum are rendered by photography when beyond the violet a vigorous action is apparent, while in the visual spectrum—according to Schmitz-Seibitz—the action is not perceived farther than line E in green. Recent experiments with bromide of silver have, however, shown me that the sensitiveness of the body may run much farther, but that if certain accelerating substances or "preservatives," as they are sometimes called, are employed the action goes as far as red—that is, it may reach a point where hitherto it has been in photography as the darkest night.

I recently received from England some "Wortley" or collodio-bromide plates. These I exposed in the spectrum, and found to my astonishment that they were more sensitive at the line E in green than at light blue to the line F. Here, therefore, I obtained a result in regard to sensitiveness in opposition to experiences hitherto reported, the film being more sensitive for colour supposed to have little chemical activity than for a vigorous chemical act. It is true not all the Wortley plates gave this result, some of them giving it but faintly, and others not at all. At first I believed the same to be due to alkaline development, and said as much, but found afterwards that an *acid* developer gave similar results. This circumstance induced me to undertake a closer investigation of the sensitiveness of bromide of silver in connection with the spectrum colours.

My apparatus I prepared with the aid of a miniature camera fitted with a Steinheil lens, and this was directed against the prism of a spectroscop. The slit was only millimetres wide. The sun's rays were thrown upon the with the aid of a Foucault heliostat, which my friend Dr. Zenker placed at my disposal; the spectrum image from D to G measured 35 millimetres. For comparative experiment I chose the time from 11 a.m. to 5 p.m., with a sky perfectly free from clouds—a time rather difficult to obtain at this time of the year. The period of exposure lasted, as a rule, about ten minutes. After exposure, the plates were developed by means of sulphate of iron. At the very first experiment I found that the sensitiveness of the bromide of silver stretched to a point much farther than Dr. Schmitz-Seibitz has shown. This gentleman only obtained an action at the ultra-violet near line F in blue. In my experiments the sensitiveness in every case was shown to extend beyond line F more or less far according to the transparency of the atmosphere.

I employed the bromide of silver in two forms: that is to say, in a moist state, with minute drops of silver solution attached to it, and, again, as dry plates produced by washing off the silver solution and drying. They acted differently. It was found that dry bromide of silver has a much greater sensitiveness for colours than bromide of silver moistened with silver solution. The latter, on development with an *acid* developer, showed sensitiveness to midway between D and E—near to the yellow, therefore; while the dry film gave a sensitiveness for 2 millimetres beyond, into the orange.

The nature of the impression on the two plates was also different. In the wet bromide of silver an exceedingly vigorous action was observed between G and F in indigo and blue. At F, however, it vanished rapidly, and only a slight action was perceptible beyond E. The dry plate showed a much weaker action in the blue than the other, but the impression went off more gradually, and reached, as already stated, as far as D.

Dry bromide of silver is therefore more sensitive for the less refrangible, and wet bromide of silver for the highly refrangible, blue rays of the visible spectrum.

For ordinary photographic plates, a solution of silver is a vigorous accelerator—that is to say it increases the sensitiveness, because it combines with the *acetic* or

bromine set free on exposure. When this action takes place principally in blue, it may be explained that the blue rays are more vigorously absorbed by the wet film than the others. I was aware, last summer, when experimenting with iodide of silver, that a body only then enhances the sensitiveness when it is not only capable of combining chemically with free iodine, but absorbs also the chemically active rays. For instance, dry pyrogallie acid, which combines with iodine, makes an excellent sensitiser, but in solution is of no avail, as it allows the chemical rays to go through unimpeded. Optical and chemical action must be combined in a body in order to be an accelerator.

As already remarked, the sensitiveness of the dry bromide plate gradually diminishes from blue to red. Of the phenomenon which I observed in so marked a degree upon most of the English bromide of silver plates—viz., a lack of sensitiveness from violet to blue, and an increase from blue to green—I observed nothing when working with bromide of silver plates prepared by myself. The explanation just referred to, of the action of nitrate of silver solution upon bromide of silver, caused me to think that the English bromide of silver plates contained a body of some kind which absorbed the green in a higher degree than the blue. So far as is known a yellowish pigment is sometimes added for the accredited purpose of checking the chemical blue rays, but it is possible that the body here employed does not absorb the blue rays, but allow them to pass, only hindering them in some degree.

The Wortley plates contain nitrate of uranium, gum, gallic acid, besides the yellow colouring matter. To ascertain whether this coating exerts any action, I washed one of the plates with alcohol and water, and obtained in that way a plate which did not show any increased sensitiveness in the green. I next essayed to impregnate bromide of silver with a substance especially capable of absorbing the yellow rays, and which combines with free bromine and iodine, in the hope by this means of improving the sensitiveness of the plate for yellow rays. I chose coralline for the purpose which Professor Liebermann kindly placed at my disposal. A very dilute solution examined under the spectroscopic gives an absorption-band between D and E, and stronger solutions cause the band to be increased beyond D; on the other hand, blue near F is allowed to pass to an appreciable extent.

I dissolved the coralline in alcohol, and added to it some of my bromised collodion, so that it became coloured of a vigorous red. With this collodion some bromide of silver dry plates were prepared, which were tinted of a reddish colour, and these, submitted to the action of the spectrum, confirmed my previous speculations; the plates showed themselves to be sensitive in the indigo portion of the spectrum, and the sensitiveness diminished towards light blue, became weak at F, then increased, and appeared in yellow as vigorous almost as in indigo. I had therefore discovered a method of producing bromide of silver plates which could be acted upon quite as vigorously by a colour held to be bereft of active chemical action—as, for instance, yellow—as by a colour such as indigo, which hitherto had been considered to exert the greatest chemical action.

After these experiments, I was led to hope than any other body capable of combining with bromine, and which would absorb red vigorously, would also heighten the sensitiveness of bromide of silver for the red rays. Such a substance I found among the green aniline colours. These absorbed vigorously the red rays midway between D and C; the absorption stretched with greater concentration farther towards D,—yellow, green, and blue, passing through almost intact. A collodion tinted with this aniline green was found, indeed, to be sensitive into the red. The sensitiveness diminished from indigo to yellow, and then increased, and, on that spot where the absorption-band had been remarked, there the film was most sensitive to red.

From these experiments we may conclude, I think, with

tolerable accuracy, that it is possible to render bromide of silver sensitive to any desired colour, improving its sensitiveness for certain colours. It is only necessary to add to the bromide of silver a suitable body which absorbs one chosen colour, but not the others. Perhaps we shall get so far as to photograph the ultra-red spectrum, just as we have depicted in the camera the ultra-violet. The till-now supposed photographic inactivity of certain colours, which is so often a stumbling-block, would then be obviated. In how far the results are of practical importance the following experiment will show:—A blue band upon a yellow ground was photographed. With an ordinary iodide of silver collodion plate, I obtained a white band upon a black ground. With a bromide of silver coralline plate, upon which blue and yellow acted with equal power, nothing could be obtained, I foresaw, and for this reason, I put in front of the lens a yellow glass plate, which absorbed the blue light, and allowed the yellow rays to pass through unheeded; and then I was enabled to obtain, after a sufficiently long exposure, a dark band upon a light ground.

The matter is, however, not simply a technical one, but also of interest from a scientific point of view. Until now we believed that the haloid salts of silver could only be chemically altered by rays which they absorb in to a notable degree, and the value of "accelerators" or "preservatives" was scarcely credited (Schultz-Sellac).

My experiments teach that in the sensitiveness of photographic plates it is not only the optical absorption power of the sensitive silver salts, but also the optical absorption power of substances mixed with them, that exercises an important influence in the matter.—*The Photographic News*.

ON THE ENERGIES OF THE IMPONDERABLES, WITH ESPECIAL REFERENCE TO THE MEASUREMENT AND UTILISATION OF THEM.*

By the Rev. ARTHUR RIGG, M.A.

(Continued from page 312).

LECTURE VII.

On the Energy of Heat, with especial reference to the Measurement and Utilisation of it.

THE energy of heat has, in one form or other, attracted more notice than that of any of the other imponderables with which this course of Cantor Lectures has to deal. Various explanations of the cause of heat being possessed of energy have been given, but it was not until the closing years of the last century that views on this question were first enunciated, which have since borne such good fruit. Count Rumford, in 1798, by an experiment in the boring of cannon in the arsenal at Munich, and Sir Humphrey Davy, in 1799, by the liquefaction of two pieces of ice by the friction of each on the other, laid the foundation of that explanation which has been so successfully generalised, and which even now is hopefully pursued.

The first question that presents itself to us is, "What is heat?" And in order to present the modes suggested for measuring it which are diagrammatically expressed on the wall, it will be needful to make some preliminary statements. In the general table of energies the sources of heat are represented as the sun and fuel. That term fuel might with very good reason have been omitted, for the one source of heat is the sun; fuel is a secondary source, having its primary in the sun. Heat obtained from the sun and the circumstances under which it is obtained are foreign to the subject of this lecture. Heat obtained from fuel, and also from the sun, is kinetic, or capable of producing motion when it is radiant, or passing from place to place; and it is potential, or stored up,

* The Cantor Lectures, delivered before the Society of Arts.

when it is absorbed. Now it was absorbed in those primeval times when there was an immense mass of vegetation on the face of the globe; that vegetation absorbed the heat. In these primeval forests it has been preserved, and in such fuel as coal it is restored. In being so restored or returned, that is given back to the earth which was absorbed perhaps before the creation of man. These buried forests are now a-glow with light, and heat, and vigour—unmistakable types of resurrection from a grave. Let us turn to that received from the sun, and refer to the diagram of the spectrum which many of you saw last week, and consider how that diagram aids in illustrating the question of heat. On Monday last an endeavour was made to explain how it was related to the phenomena and energies of light, and incidentally to the phenomena and energies of chemical affinity. One portion is related to the energy of light, properly so-called; another portion is related to the energy of affinity, properly so-called; and in this portion, which is perfectly obscure, and which escaped notice until recent years,—in this which is invisible to the human eye, although it may be visible to the eyes of other animals, lies that which we call solar heat. You observe that to the spectators' left-hand of the portion marked with the usual prismatic colours there is a shade of red extended to a length equal at least to that marked with such decided colouring. It is not far from the truth to say that in this lies all the heat from which we obtain our stock of motion. It may be desirable to explain how we know that the heat lies there, and why the diagram is there drawn, and extending to such a distance from the visible portion of the spectrum, and that in such portion lies the greatest amount of heat. It is done in this way:—We take a little instrument called a line thermopile, composed of a number of strips of metal laid edge to edge, and soldered at the alternate ends. The two metals are usually antimony and bismuth. The pile is in the form of a straight line, because it is to be used for determining the heat at a particular portion or line across the spectrum.

Thermometers for heat purposes may be said to be useless, and, perhaps, before going further, it may be well to state why they are so. A thermometer is an instrument which, by the expansion of a fluid, as air, or a liquid, as alcohol, mercury, &c., or by any other means, tells us the difference in temperature between two bodies. If a thermometer be placed in water, it would tell us how much the temperature of the water is above the freezing-point, or how much below the boiling-point. But freezing- and boiling-points are neither of them standard points. There is heat far below the freezing-point, and there is heat still higher than the boiling-point; and indeed there is no approachable zero from which to commence the graduations of a thermometer. We want, too, another thing, not relative heat but absolute heat. Another means for obtaining records of heat is by the use of the thermopile and a galvanometer. This galvanometer is connected with the thermopile, and the speck upon the screen is that to which we have to look. If two short thin wires, one silver and the other copper, be taken, one wire attached to one end of that round the galvanometer, and the other to the other end, questions in relation to heat, and electrical phenomena in connection with it, may be made clear. If the free ends of the silver and copper wire be placed in contact and held between a finger and thumb, or placed near a lamp-flame, the speck immediately moves, and travels over a large space. No thermometer is so delicate or sensitive to heat as this combination of instruments. The heat which in a thermometer would be employed in expanding the liquid is in this case converted into an electrical current which affects the galvanometer. Heat in the one case is measured by the expansion of a liquid, in the other by being converted into electricity, and the electricity is measured, as explained in a previous lecture, by the galvanometer. The speck is now steady, but on

taking hold of the junction of the wires the speck moves in consequence of the simple touch of a finger. If the junction be once waved near the flame of a lamp, the speck moves directly—evidently there is a real and measurable energy in the heat which has passed. It should be remembered that this galvanometer requires quantity of electricity, and not what is called intensity. That motion, therefore, by being properly measured, enables us to get, inferentially, at the quantity of heat. The measurement of heat by differences of temperature is called "thermometry." The measuring of an absolute quantity of heat is called "calorimetry."

These metals thus indicating heat by the conversion of it into electricity are applied here in a line, and if this apparatus is placed in front of a real spectrum, of which that on the wall is a pictorial diagram, and moved gradually along by means of a fine-threaded screw, the line thermopile passes into successive portions of the spectrum, and according to the amount of heat in each portion, so the galvanometer deviates. If, therefore, the galvanometer at one portion is sent further aside than at another, we know it is owing to a larger quantity of heat being converted into electricity. Such an arrangement was carried out, and the largest amount of heat was found to be where that high mountain is marked on the drawing. This much must at present suffice for showing how to determine and measure the quantity of heat.

Now let the consideration be how this heat is converted into motion. Motion, we know, produces heat, but here the converse question is presented—heat producing motion. If we can show that heat produces motion, and if we know that motion produces heat, those two are mutually interchangeable. That no motion can take place without the development or absorption of heat may be made manifest by an experiment. Here is a thermopile, rather more delicate than the one hitherto used. Here is an air-pump, connected with which are two copper vessels separable by a tap. If, now, the air be exhausted from one of these vessels, the one nearest to the air-pump, it then becomes empty, and if the thermopile be caused to touch the other vessel, or to touch this one, which is empty, and the speck of the galvanometer is stationary; then, when the tap that separates the two is opened, air rushes from one into the other, and the galvanometer speck indicates a change in the heat relationships of the two vessels. These changing heat relationships result whenever action takes place. If a thermopile having a larger surface, intended for the purpose of investigating very delicate changes of temperature, be attached to a condenser which serves to increase the surface and so to magnify the result, it would be found that by merely touching one portion the speck of the galvanometer moves. Now, if a fan be caused to act in front of and upon the thermopile, the impression would be that we should withdraw heat. The withdrawal of heat may be produced by the blast of air, but this air striking on the thermopile causes the spot of the galvanometer to move in the direction indicating an increase of heat. The question is, whence comes that increase of heat? The answer is, that heat comes from my arm, and is produced by muscular energy being converted into mechanical power, which is then transformed to heat, which is changed into electricity. In this case the energy passes direct from my arm through the fan, and propels a current of air against the thermopile. If, however, the draught of air upon the thermopile, instead of being direct from my hand had been treated in this way,—if a close vessel had been taken, and by means of a condensing syringe, air had been forced into it, and allowed to remain for a few minutes, and then jetted against the thermopile in the same way as the air from the fan—we should find, after the first impact of air, that cold and not heat had been produced. Therefore the one blast blows hot, and the other blast blows cold. Thus, *Æsop's* fable of the man and the satyr appears to be realised. Much confusion has arisen from the use of the word cold, as though it was something distinct from heat.

"Cold" is only a condensation of the phrase "decrease of heat." Conflicting views would sometimes be harmonised were this word disused, and the word "heat" employed with a proper prefix.

There is a very good reason to be given for these results. The case of a blast producing decrease of heat may be illustrated thus:—In this iron bottle there is some condensed carbonic acid gas, which is under a pressure of about 700 lbs. on the square-inch. Now, it might be expected that as the blast from the fan produced heat, so the blast from this bottle of condensed gas would also. A jet of this condensed gas is now directed to the thermopile; the reflected light of the galvanometer by its motion indicates that the current has produced cold. It certainly appears remarkable that in the case of one blast heat is manifested, and in the other cold is produced. The explanation is this:—In neither case can the air be put into motion, except by the expenditure of heat. In the case of a fan the heat is at once expended in causing a blast of air, but in the other case the heat is expended in the previous act of condensation. When this condensing syringe has been used for two or three strokes, the cylinder of the syringe has become hot. The process of heat radiation is continuous. As soon as that bottle was filled, the heat accumulated in the work of condensation began to radiate. In other words, the muscular energy, which condensed the gas into the bottle, was dissipated in the form of heat. The contents of the bottle require an expenditure of that which may be represented by as much heat to get out of the bottle as they required to put them in; therefore this heat must be drawn from some source or other, and the first supplies are drawn from the contents of that which was in the bottle. The paradoxical and apparently contradictory phenomena are, however, reconcilable in a most instructive manner. In the case of the fan the blast carries the muscular energy converted into heat direct to the thermopile. In the case of the bottle this heat has been dissipated by radiation.

Let us now consider and describe how Mr. Joule obtained that which has become the basis of our calculations, and the arithmetical measurement of heat, namely, 772 foot-pounds as the mechanical equivalent of the amount of heat required to raise 1 lb. of water through 1° F., or 1390 foot-pounds for raising the same quantity of water through 1° C.

His experiments extended over about seven years, and the first apparatus used was the one shown in this diagram. There is a small vertical shaft capable of being rapidly turned by a handle: across or through the shaft is a short glass tube, in which were introduced a number of bars of wrought-iron. These were covered with oiled paper, so separating them electrically one from the other. The bundle was wrapped round with copper wire, and then inserted into the glass tube, which was closed at one end with a cork, and capable of being closed at the other. That glass tube was coated with tin-foil, so that in fact the tube was very like what is called a Leyden jar. It had an electrical coating inside and out, the only peculiarity being that a slit was cut along the coating on the outside of the vessel to prevent electrical induction. The tin-foil was then covered by strips of wood parallel to the tube, and bound all over with silk. The ends were corked, and also covered with oiled silk, so as to close it thoroughly. From the inside of the tube two wires passed down and dipped into two mercury cups, which were connected with a galvanometer, so that currents of electricity, if any were produced in the interior metal bars, would be manifested by the galvanometer. On each side of this short glass tube were fixed two arms of wrought-iron, bent in the form of a horse-shoe, and as nearly in contact with the ends of the glass as possible. This wrought-iron horse-shoe had a coil of copper wire round it, and by the usual means it could be converted into an electro-magnet. A certain weight of water was put into the short glass tube along with the bars, and having rotated the instrument for a quarter of an hour, the temperature of the water

when examined was found to be hotter than before. The galvanometer being observed it was known what electricity had passed, and this, combined with the change that had taken place in the temperature of the water after fifteen minutes rotation of the shaft, at the rate of six hundred rotations per minute, sufficed for determining the amount of electricity converted into heat. Thus, approximate data were obtained on which to found other experiments. Such experiments were made and re-made, they failed, and were again renewed; and to note how Mr. Joule overcame one difficulty after another, until he succeeded, furnishes a beautiful example of perseverance. Sometimes where he expected to find a substance had gained heat, he found, on the contrary, it had lost. Such anomalies, however, were afterwards completely accounted for.

Research in science claims the exercise of much ingenuity under unexpected and baffling conditions. The perplexity just described became an element in success. Mr. Joule availed himself of the process of "interpolation," and so adopted what proved of great assistance in future experiments. What has been described was the earlier of many processes. Next, he found it needful to measure the energy exerted upon the handles, because if in this vessel a quantity of heat had been generated which produced an observed increase of temperature in the water, it was desirable to know what was the value of the mechanical energy, which had caused that heat to be so generated. If motion be given by the hand only, there is no means of measuring that value. The earlier object was to see if heat could be obtained; then the next object was to measure the heat obtained, and also to measure the mechanical energy by which it had been obtained. The apparatus now assumed this form. He gave up the electrical process, and began to take a vessel, similar to the one shown in this diagram, which had brass plates in it, and brass bars fixed to the inside of the vessel, and running across, so that paddles could rotate between the bars. The vessel was filled with water, and therefore, when the paddles rotated, the fixed bars stopped the whirl of the water, and heat was developed. The sea, as those who are accustomed to bathe know very well, is warmer on a windy day than on a calm day, simply because the motion of the water caused by the wind is converted into that motion of the molecules of the water which we call heat. So in the experiments with this apparatus, the motion of the water in the vessel is converted into the motion called heat. Of course all possible means were adopted to prevent heat passing by radiation from the exterior of the vessel. Hence the vessel was enclosed in another, and that again in another. The contrivances for ascertaining a measure of the mechanical effort made to keep the paddles rotating at a uniform rate were very simple.

The little vertical shaft on which the paddles were fixed was prolonged upwards, being divided across and re-connected in line by a piece of vulcanite, which, in common phraseology, would be called a non-conductor of heat. Wound round the upper part of this shaft were two cords, the ends of which passed over two pulleys on opposite sides. To these cords were fixed weights, by the descent of which motion could be given to the paddles. The cords were two in number, and on opposite sides, in order to obviate as far as possible the heating effect of rubbing friction on the shaft journals. With this apparatus, and others constructed upon similar principles, a series of experiments enabled him to arrive at certain definite conclusions.

In a research of this kind, made with apparatus contrived as new thoughts and new experiments suggested, it was not to be expected that the tabulated results should speak with one consenting voice. They did, however, seem to proclaim this—that the mechanical equivalent of heat competent to give an increase of temperature of 1° Fahrenheit to 1 lb. of water, was between 500 and 800 foot pounds. Detecting and

eliminating those elements which seemed to affect the accuracy of the result, he was enabled at last to come to this conclusion, that 772 lbs. was the exact number which was the mechanical measure, or, as it is commonly called, the mechanical equivalent of heat. That means this—he found how much a known quantity of water was raised in temperature by a recorded mechanical exertion, and he deduced the measure of that exertion needful to raise 1 lb. of water 1° on Fahrenheit's thermometer. Thus he found that that heat, applied to raise weights, would lift 772 lbs. through one foot; that is, if you had 772 lbs. weights here, and lifted them a foot high, it would be the same thing exactly as applying the same force to 1 lb. of water, and raising the temperature 1° Fahrenheit.

There is a table written out mathematically, by means of which the 772 lbs. are deduced. Mr. Joule having made these experiments, others followed, and we have a table showing the means used, air, friction, steam, Daniell's battery, electro-magnetism, &c.; also the names of the experimentalists, and the mechanical equivalent of heat, as determined by them. Although the results differ from Mr. Joule's 772 lbs., yet his figures are now generally adopted.

The title of this lecture includes the words measurement and utilisation. The utilisation of heat is so important a commercial as well as scientific question, that there are one or two matters bearing upon it which may be worth present attention and much future thought from all. That we do not obtain in a steam-engine more than a quarter of the heat we expend in the furnace is now generally recognised. There is a table here, based upon Mr. Joule's calculations, which gives the number of horse-power—a technical term, meaning 33,000 units of work, which could be obtained by utilising the heat required for passing nine pounds of ice through its physical and chemical changes. If we have 9 lbs. weight of ice, and attempt to melt and convert them into liquid, a certain amount of heat is absorbed or rendered "latent," as it is called. At any rate there is a quantity of heat that does not show itself upon the thermometer. Then, after it is converted to water, if we gradually raise the temperature to 212°, there is another large quantity of heat rendered "latent" in the conversion of this water into vapour, and if we then convert that vapour which comes from the water into its elemental gases, viz., oxygen and hydrogen, another large quantity of heat is absorbed or rendered "latent." Now take that process backwards; assume we can take this 9 lbs. of oxygen and hydrogen and re-convert them back again into ice, and that it was in our power to use the heat which had been given off, then we get the quantity shown in the table. If we burn a quantity of hydrogen in oxygen it is converted into water; if one part of hydrogen and eight parts of oxygen are combined by an electric spark or other means, and converted into water at 212°, a number of units of heat equal to 1451 horse-power are obtained. If, then we pass it still further into the form of water at 32° we should obtain 38 horse-power more; and if we then pass it from the form of water into the form of ice, we should obtain 30 horse-power. Therefore, if in obtaining 9 lbs. of ice from its primeval elements, viz., 1 lb. of hydrogen and 8 lbs. of oxygen, we could utilise as a mechanical agent all the heat set free, then from the data given we see that there would be obtained 1519 horse-power of work. But we cannot obtain this. What becomes of the heat, where it goes, and why we cannot contrive to utilise it, are inquiries which yet perplex scientific students. Various surmises have been made, but none of them have been accepted, except as the vague guesses of an unsolved riddle, the best of which are taken, though there remains a lurking feeling that none of them are right.

There is another table bearing on this question, viz., the advantage of using steam at a higher pressure than what is called low-pressure steam. If we take water at 32°, that is just above the temperature of ice, and that

be warmed until it attains the temperature 213°, it would occupy a bulk 1669 times as large as it was in the form of water. There is a relation between the pressures and temperatures which must be maintained, in order to preserve the whole of the water in the form of steam. These relations are expressed in the first two columns in the following table. The third column expresses the resulting volume of steam. The fourth column is the product of the pressure and the volume, and, therefore, represents the mechanical value of our unit of water. How much and at what rate this value or power increases with an increase of heat, and a correspondent increase of pressure, may be known by considering the figures in this fourth column. These figures represent the advantage of using steam at high pressures, and, therefore, high temperatures:

STEAM FROM WATER.

Pressures.	Temperatures.	Volumes.	Pressure multiplied by volume.
lbs.	Deg. F.		
15	39	1	
15	213	1669	25,035
25	240	1042	26,050
35	260	765	26,775
45	275	608	27,360
55	288	506	27,830
65	299	434	28,210
75	308	381	28,575
85	317	340	28,900
95	325	307	29,165

The reason why we cannot work steam at some of these very high temperatures is this, that when we superheat it, we thereby prevent any of it being converted into vapour, and if it is not so converted into vapour we have no means of lubricating the faces of our slide valves, and the consequence is, the metals being heated, they soften, then scratch and tear each other's faces, and the engine is soon destroyed. As soon as we can get slide-valves made of some material which will bear this higher temperature without abrasion or scratching, then, probably, we shall be able to work superheated steam economically.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 18, 1873.

Dr. ODLING, F.R.S., President, in the Chair.

THE names of the visitors having been announced, and the minutes of the preceding meeting read and confirmed, Mr. Robert Williamson was formally admitted a Fellow of the Society.

The names read for the first time were those of Messrs. Howard Barrett, Thomas Pemberton Wiltshire, George Whewell, and John Young.

For the third time—Messrs. Edward H. Davies, Sydney Trivick, John Smyth, M.A., Edmund Richard Southby, Edward Daniel Stone, John Sutherland, Carl Schörlemmer, F.R.S., and John Clement Souter, who were then balloted for and duly elected.

THE PRESIDENT said the Fellows would doubtless remember a paper read before the Society, "On the Dioxides of Calcium and Strontium," by Sir J. Conroy; he had received a letter from Dr. E. Schöne, of Moscow, in which he pointed out that, as early as 1866, he had published a description of these compounds in the *Bulletin de la Société Imperiale des Naturalistes de Moscou*, and which has also appeared in the *Ber. d. Deutsch. Chem. Ges.*, vi., 1172. Dr. Odling had also received another reclamation, from Mr. Horsley, with respect to Mr. Donkin's pro-

cess for determining the amount of nitrates in water, recently communicated to the Society, but he employs pyrogallie acid (CHEMICAL NEWS, vol. 28, p. 254) instead of phenol, and only as a qualitative test, not as a quantitative method.

The first paper, "On the Preparation of Standard Trial-Plates to be Used in Verifying the Composition of the Coinage," was read by the author, Mr. W. CHANDLER ROBERTS, Chemist to the Royal Mint. After sketching the history of the composition of the alloy employed for the English gold and silver coins, the author gave a table of the composition of the five gold and silver trial-plates since 1660, showing that they sometimes varied considerably from the standard of 916.66 for gold and 925.0 for silver. The alloy in the last gold trial-plate, that of 1829, consisted of equal parts of copper and silver, but since 1837 the coin itself has been alloyed with copper alone. The new trial-plate has been prepared by melting together pure gold and copper, the purity of which was guaranteed by its high electric conductivity; of course, repeated meltings were necessary before the proportions of the metals had been correctly adjusted. Assays of pieces taken from various parts of the plate showed that it was homogeneous. Much difficulty, however, was experienced in preparing the silver trial-plate, owing to the tendency which the alloy, when cast into bars, has to be richer in silver in the interior than on the exterior, as shown by the experiments of Levöl. In order to overcome this, it was necessary to resort to an artifice—casting the metal in the form of a hollow cylinder, which was then cut open and rolled; this did not succeed, the upper and lower portions of the casting possessing different compositions. 1000 ozs. of standard silver were therefore cast into a plate 30 centims. long, 25 wide, and 5 thick, the surface to the depth of 4 m.m. being subsequently planed off. This was then rolled out, and portions of metal removed from all parts of the sheet for assay. By this means it was found that a comparatively small portion along one edge of the plate was homogeneous and to have the required composition; the rest of the sheet was removed, and this portion is reserved as the standard trial-plate. Owing to the impossibility of obtaining plates of alloys which shall be absolutely homogeneous, the author suggested to the Lords of the Treasury to supplement the standard plates by plates of perfectly pure gold and silver. The gold plate was precipitated from more than 100 gallons of solution of auric chloride by means of oxalic acid, and the silver plate was prepared by Stas's process of reducing an ammoniacal solution of argentic nitrate by ammoniacal cuprous sulphite. [The trial-plates were exhibited, as also a magnificent specimen of crystallised gold.]

The PRESIDENT having thanked the author for his communication, Mr. H. W. FIELD said his own observations quite agreed with those of Mr. Roberts. In 1852, under Sir John Herschel, the use of fine gold as a comparison for the standard was introduced; for this purpose pure gold was obtained, and from that time the coin had been made according to the standard of 916.66, and not according to the trial-plate of 1829, which was only 915.5. He had compared some of the earlier coins with the plates, and had found a great variation from the standard.

Mr. RIDSDALE said he had in his custody some of the earliest trial-plates, including that of 1447, in Edward IV.'s reign, of 99.48; on Oct. 16, 1660, this was changed for the new standard trial-plate of 916.66. He had not examined all the trial-plates.

Mr. H. J. CHANEY, of the Standards Department, said they were greatly indebted to Mr. Roberts for the care he had taken in preparing the new trial-plates, and desired to thank him on behalf of the Warden of the Standards.

Dr. BOYCOTT remarked that the gold alloyed with silver and copper was harder and wore much better than that alloyed with copper alone. He could confirm Mr. Roberts's remarks on the irregularity in composition of silver bars; in Mexican dollars, the bars for which were cast just the width of the coin, the centre of the coin varied considerably

from the edges corresponding to the edge of the bar; in crown pieces, too, the centre usually contained more silver than the edges.

Mr. MAKINS was surprised to find that Mr. Roberts had such difficulty in obtaining silver bars of uniform composition. Levöl's experiments were made on small quantities cast in iron moulds. The speaker had found that bars cast in very hot sand and slowly cooled were very uniform in composition throughout, and those cast in red-hot iron moulds were almost as good.

Mr. ROBERTS replied that he had tried casting at all temperatures; he had surrounded the moulds with ice, and he had used them red-hot, but he had not been so fortunate as Dr. Boycott, for he had never succeeded in obtaining homogeneous bars by this means.

Mr. CHANEY observed that the Warden of the Standards had been in communication with both Stas and Peligot on the subject, and they admitted that it was impossible to produce bars of these alloys which were perfectly homogeneous.

A communication, entitled "Researches on the Action of the Couple on Organic Bodies" (Part IV., "On Iodide of Allyl"), by J. H. GLADSTONE, Ph.D., F.R.S., and A. TRIBE, F.C.S., was read by the former. The action of the dry couple on allyl iodide at 100° gave rise to diallyl and a non-volatile resin, $n(C_3H_4)$, apparently isomeric with allylen; no gas was evolved, neither was any organic zinc compound produced, the principal reaction being—

The production of the polymeric of allylen the authors attribute to the zinc oxide unavoidably present in the couple. Unwilling to relinquish the hope of obtaining zinc allyl, they tried the action of the couple on the iodide in the presence of ether, but the result was substantially the same, no zinc allyl appearing to be produced. The action of the iodide on the couple moistened with water proceeds rapidly, giving rise to propylen, the reaction being $C_3H_5I + H_2O + Zn = ZnHO + C_3H_6$. The couple acts so violently on allyl iodide in presence of absolute alcohol that the experiment was modified by substituting for it granulated zinc, and even then the action becomes unmanageable unless the apparatus is kept cool. Alcohol of sp. gr. 0.805 acts more slowly, owing to the retarding influence of the water. The gas evolved is pure propylen, and the reaction thus affords an easy method for preparing that hydrocarbon; for this purpose, some granulated zinc and absolute alcohol are placed in a flask furnished with a delivery-tube and thistle-funnel, allyl iodide being gradually added as the gas is required—

Dr. ODLING, while thanking the authors for their interesting communication, enquired whether the action of the couple continued as long as any zinc remained.

Dr. GLADSTONE replied that it did, although the action became slower as the amount of zinc diminished.

Dr. WRIGHT said he felt some interest in the fact that the allylen was polymerised at the instant of its formation, and not given off as such; a similar reaction took place in the decomposition of sulphovinic acid, where polymerides of ethylen of high boiling-point were simultaneously produced. He might also mention that some time ago a process was patented for the preparation of aniline from nitro-benzol by means of a copper-iron couple prepared by treating the iron with a dilute solution of cupric sulphate.

Dr. R. SCHENCK read a paper "On Tetranickelous Phosphide." On pouring a solution of nickelous chloride into a boiling solution of potassic hydrate to which phosphorus has been added, a brown precipitate is immediately formed, which is soluble in dilute acids, but in a few minutes a black substance, insoluble in acids, begins to be formed; this, after purification, was analysed, and found to correspond pretty nearly with the formula for an oxyphosphide

of nickel, $\text{Ni}_4\text{P}_2\text{O}_4$. The experiment was accordingly modified by previously adding to the solution of nickelous chloride enough tartaric acid to prevent the precipitation of nickelous hydrate by the potash; the product, on analysis, was then found to have the composition Ni_4P_2 . When ignited in a current of hydrogen, the black compound changed its colour to dark grey, contracted in volume, and became much harder. The phosphide dissolves very slowly in dilute hydrochloric acid, readily in dilute nitric acid. In aqua regia it dissolves sometimes slowly sometimes quickly, as also in sulphuric acid. It is not magnetic.

The PRESIDENT thanked the author for his communication on this little-studied class of bodies. The tetranickelous diphosphide belonged to a class of compounds analogous to the sub-salts of copper in which the metal acted as a quasi-moanad; there was also a similar insoluble subsulphide of nickel.

Dr. WRIGHT remarked that the action of carbon monoxide on the oxides of iron, cobalt, and nickel, gave rise to suboxides of these metals, having the compositions Fe_2O , Ni_2O , Co_2O , in which the metals appeared univalent.

Dr. SCHENCK said the action of phosphoretted hydrogen on the metals, kept in solution by tartaric acid, produced phosphides much richer in phosphorus than those obtained from the hydrates, but he had not yet examined them.

A note, "*On Ferrous Anhydrosulphate*," was read by the author, Mr. T. BOLAS. On mixing a cold saturated solution of ferrous sulphate with nine times its volume of concentrated sulphuric acid, a white crystalline powder is deposited as the mixture cools, or immediately if the solution of iron is supersaturated. When microscopically examined, this powder is seen to consist of minute prismatic crystals, resembling Glauber's salt in form. Collected by means of a Bunsen's pump, and dried on a porous tile, they were found to have the composition of ferrous anhydrosulphate, FeS_2O_7 . Exposed to moist air, they absorbed water, and gave a salt of the composition $\text{FeSO}_4 \cdot 6\text{H}_2\text{O}$, but, when treated with water, they yielded crystals of ordinary green vitriol, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$. The author is engaged in the examination of the precipitates produced by oil of vitriol in solutions of other metallic sulphates.

The PRESIDENT having thanked the author for his communication, Dr. C. R. A. WRIGHT read a paper "*On the Hydrochloride of Narcein*," in which the author said he could corroborate Petit's statement that, in order to obtain the normal hydrochloride of narcein, it was necessary to have a large excess of hydrochloric acid. With 8 or 10 eqvts. of the latter, the salt was obtained, apparently having the composition $\text{C}_{23}\text{H}_{29}\text{NO}_9 \cdot \text{HCl} \cdot 2\frac{1}{2}\text{H}_2\text{O}$. When this was dissolved in fifty times its weight of boiling water, fine filamentous crystals were formed at 35° , having the composition $6(\text{C}_{23}\text{H}_{29}\text{NO}_9)\text{HCl}$. On thoroughly washing these with cold water, they lost hydrochloric acid, leaving a body of Petit's formula, $10(\text{C}_{23}\text{H}_{29}\text{NO}_9)\text{HCl}$, but it is doubtful if this is a definite compound, as it still loses hydrochloric acid by repeated crystallisation. Owing to the obstinacy with which the hydrochloric acid adheres to narcein, it has not hitherto been practicable to obtain it absolutely free from chlorine. This, the author thought, might be due to the presence of a chlorine derivative of narcein analogous to chlorocodide, but no evidence of the existence of such a body could be obtained, the action of strong hydrochloric acid on narcein, giving rise to a hydrochloride of a base having the formula $\text{C}_{23}\text{H}_{27}\text{NO}_8 \cdot \text{HCl}$. The new base is amorphous, sparingly soluble in ether, and its salts yield a dark blue-purple colour with ferric chloride.

The PRESIDENT said they were much obliged to Dr. Wright for his paper on this portion of his researches on the opium bases.

The meeting finally adjourned until Thursday, Jan. 15, 1874, when the following papers will be read:—"On the Action of Trichloracetyl Chloride on Amines (I., Action

on Aniline)," by Dr. Tommasi and Mr. R. Meldola. "Researches on the Action of the Copper-Zinc Couple on Organic Bodies (Part V., On Ethyl Bromide)," by Dr. J. H. Gladstone and Mr. A. Tribe.

NOTICES OF BOOKS.

Quantitative Chemical Analysis. By Dr. C. REMIGIUS FRESenius. Sixth Edition, Translated from the Fifth German Edition by A. VACHER. London: J. and A. Churchill.

THE chemical world at large has long ago come to a conclusion as to the merits of the original work of Fresenius, and we, at least, see no grounds for appealing from its verdict. In noticing the present edition, our business, therefore, is merely with the translator, and the manner in which he has fulfilled his duties. When speaking of the fifth English edition, we had occasion to express our disappointment at its wide departure from the original. We learn from Mr. Vacher's preface to the work now before us that Dr. Fresenius took a similar view. To abridge or condense a book of this kind is only possible by impairing its usefulness, and by omitting more or less those seemingly minute, but not the less necessary, precautions which the author's wide and prolonged experience had suggested. We are therefore unfeignedly glad to find the "*Quantitative Chemical Analysis*" once more appearing in an English dress unabridged, and with its known and approved peculiarities. We confidently expect for this edition a wide and rapid sale among students and chemists who have been unable to meet with a copy of the fourth edition, and who all will rejoice with us to find Fresenius "is himself again."

CORRESPONDENCE.

SEPARATION OF IRON AND ALUMINA.

To the Editor of the Chemical News.

SIR,—The separation of alumina from iron is occasionally a point of slight difficulty with those who are unable to procure pure alkalis; it may be of interest to some to be made aware that a boiling solution of barium hydrate answers the purpose perfectly well. The iron sesquioxide may be dissolved in sulphuric acid, reduced with zinc, and titrated by permanganate or bichromate, and, the barium having been extracted by similar means from the filtrate, the precipitated barium sulphate is to be separated by decantation and washing, when, in the liquid thence obtained, the aluminic hydrate is precipitated by ammonia with the usual precautions. The estimation of the iron, if performed volumetrically, is scarcely, if at all, interfered with by the presence of barium sulphate, so that it is scarcely worth while to separate the latter before titration.—I am, &c.,

F. MAXWELL LYTE.

Chemical Laboratory, 6, Cité de Retiro,
Rue de Faubourg St. Honoré, Paris,
Dec. 17, 1873.

ANALYSIS OF CIGAR-ASH.

To the Editor of the Chemical News.

SIR,—I am obliged to Mr. Simmonds for calling attention to the error in the analysis of cigar-ash. I find that 5.764 per cent of sodium sulphate has been omitted, which will bring the result to 100.—I am, &c.,

A. PERCY SMITH.

Hertford, Dec. 15, 1873.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Bulletin de la Societe Chimique de Paris, tome xx., Nos. 8 and 9, November 5, 1873.

Detection of Blood Spots by means of Tungstate of Soda.—M. Sonnenschein.—Tungstate of soda, strongly acidulated with acetic or phosphoric acid, throws down albumenoid matters from very dilute solutions. These precipitates, insoluble in a large excess of water, dissolve in alkalies, especially if hot. If defibrinated blood is treated with this salt, a red-brown precipitate is formed, which becomes clotty on boiling. All the colouring matter is thrown down. To detect blood spots by this means on clothing, &c., the suspected portion is cut off, and, after having been treated with distilled water, the filtered solution is precipitated with the above reagent. The precipitate, washed and treated with ammonia, takes a reddish-green colouration. If phosphoric acid is present, it must be carefully washed away before treating the precipitate with ammonia.

Toxicological Detection of Phosphorus in Presence of Fatty Bodies.—Van Bastelaer.—The liquid is repeatedly shaken up with ether; the ethereal extract is evaporated, under protection from dust. At the end of the operation, a few drops of distilled water are added to hinder the action of the air upon the phosphorus. Under the water is deposited a liquid globule, composed of phosphorus and fat. This is placed in a small tube, and agitated with strong ammonia at 21°; the ammonia is removed by washing, first with very dilute sulphuric acid, and then with water. The phosphorus then remains, with all its physical and chemical properties.

Hepatic Ferment.—M. Wittich.—The author proves that the hepatic ferment exists in the cells of the liver, and is not derived from the blood traversing that viscus.

On Albumenoids.—M. Eichwald.—The author combats the theory of Schmidt on the coagulation of fibrin. He proves experimentally that coagulation may take place when the paraglobulin or plastic fibrin has been completely removed, and is even hastened by the action of carbonic acid. Fibrin is thrown down on neutralising the blood with carbonic acid. The albumenoids are composed of one and the same substance, modified by its combinations with colloidal and crystalloidal bodies.

Casein and Coagulation.—F. Soxhlet.—The author considers the alkaline aluminates, and casein as identical. He ascribes the coagulation of milk under the influence of pressure to the transformation of milk-sugar into lactic acid. This view is combatted by M. Heintz in another paper on the same subject.

Application of the Waste from the Manufacture of Bone-Gas to the Preparation of Pure Sal-Ammoniac.

—J. V. Divis.—The purification of the ammoniacal salts from the waste of bone-gas works and animal-charcoal works is rendered difficult by the presence of empyreumatic animal matters (Dippels's oil). The crude products have to be re-sublimed, which materially adds to the cost of production. The neutralisation of the condensation-waters with hydrochloric acid occasions a nuisance on account of the presence of ammoniacal sulphide and cyanide. The author has found a method of purification which may be used even in sugar-works which prepare their own bone-black. According to the quality of the bones, from 8 to 10 per cent of ammoniacal water may be obtained, containing from 7 to 9 per cent. of actual ammonia. The yield of bone-oil is 1.7 to 2 per cent. The ammoniacal waters are collected in old petroleum casks, and after standing for two days the supernatant oil

is decanted off. The water is then gently heated, and exactly neutralised with hydrochloric acid, after having been mixed with a concentrated solution of chloride of calcium to decompose carbonate of ammonia, without which there would be liberation of gas. Carbonate of lime is deposited in abundance, and its precipitation clarifies the liquid. After some hours it is decanted, when the sediment forms a good manure. The chloride of calcium must not be in excess, but rather slightly deficient. The decanted solution is clear and yellowish. It is heated to boiling in a sheet-iron tank, which causes the rest of the impurities to separate out when they are skimmed off. The boiling liquid is then filtered over a mixture of wood charcoal, animal charcoal, and coke placed in a double-bottomed cask. Finally the clear liquid is evaporated in shallow pans, the vapours given off being forced through the ash-grates of the furnaces. The sal-ammoniac thus obtained contains 95.3 per cent of true chloride of ammonium, and 4.2 per cent of water.

Use of the Aluminate of Soda to Preserve the Back-Cloths used in Calico Printing.—M. Kiemeier.—This invention refers especially to printing aniline blacks. The author dresses these cloths with aluminate of soda thickened with starch. This salt, by its alkaline reaction, destroys the aniline black, so that the piece may be perfectly purified after having served as back-cloth, and may even be ultimately printed. The use of aluminate of soda presents another advantage; the aniline black is destroyed on the "wrong side" of the pieces that are being printed, and as the black does not penetrate through the cloth, its fibre is less injured.

Tartar Substitute in Grain Dyeing.—M. Malfait.—This project has been commented on in Reimann's *Färber Zeitung*, and a notice of it extracted from that journal.

Antimony Blue.—C. Kraus.—The author obtains this colour by the improved process of boiling tartar-emetic with yellow prussiate of potash, and adding hydrochloric acid. The same colour may be produced, though less easily, by boiling the prussiate with hydrochloric acid, without the antimony. The antimony does not enter into the composition of this colour, but merely facilitates its formation, and may be replaced by mercury. The blue colour is, of course, merely a modification of Prussian blue, and has no right to the name of "antimony blue."

New Aniline Colour (Cinnamon-Brown).—This colour yields, on wool, silk, and cotton, a fine brown, which may be varied at pleasure by the addition of blue, red, or yellow dye-ware. On silk and wool it is applied without mordant. It is dissolved in warm water, and filtered after cooling. For silk it is acidulated with tartaric acid. For wool, 1 kilo. of sulphate of soda, and 250 grammes of sulphuric acid are taken to 20 kilos. of wool. The dyeing is performed at a boiling heat. Cotton is previously mordanted with tannin. Cinnamon-brown is obtained by means of one of the products formed in the manufacture of magenta. It is an acid salt of crysotoluidin, $C_{21}H_{21}N_3$, a base derived from toluidin by the elimination of hydrogen— $3C_7H_9N - 3H_2 = C_{21}H_{21}N_3$. The base is insoluble in water, and is separated from the solution of its salts by alkalies, in the form of a light yellow precipitate. Its neutral salts are sparingly soluble in boiling water, which splits them up into an insoluble basic salt and a soluble acid salt. The solution of the acid salts is of a yellowish-brown colour; the alcoholic solution of the free base is a pure yellow. This shade is obtained on dyeing in a bath of the acid salt mixed with an alkali.

Manufacture of White-Lead, and Accidental Products which may be Formed on the German Method.—C. von Weise.—The German process for white-lead making is a modification of the Dutch. Sheets of lead are exposed, in spacious and closed chambers, to the joint-action of air, vapour of water, and acetic acid, and of carbonic acid. The product is greyer than that produced by the Dutch method, and covers as well. It

covers better than the white-lead of the Clichy process; it is denser, finer in grain, and never crystalline, and requires less oil for painting. The German process yields a product more constant than the Dutch, as it is easy to regulate the access of air, of carbonic acid, and of the acetic vapour. Nevertheless, the progress of the operation presents certain difficulties which require much experience, and products may be formed which affect the whiteness and the covering properties of the ceruse. The best ceruse has the composition $2\text{CO}_2\text{PbO} + \text{PbO}, \text{H}_2\text{O}$. There are good specimens containing rather less hydrate of lead, but if the proportion of the latter becomes too low, the product is hard and unfit for use. In general, a ceruse is better the more hydrate of lead it contains, within certain limits. The injurious influence of an excess of carbonic acid is due to the crystalline structure which the product assumes. A sample of crystalline ceruse has a composition very like that of the neutral carbonate. The residues, likewise very hard, obtained by sifting and levigating the crude product approximate also to this composition, and are useless as a colour. In fine, the qualities of white lead may be classed according to their composition:—

	PbO.	CO ₂	H ₂ O.
1. First quality	86.80	11.16	2.00
2. Second quality	86.24	11.68	1.81
3. Third quality	86.03	12.28	1.68
4. Residues, very bad	84.69	14.10	0.93
5. Abnormal product, useless..	83.47	16.15	0.25

The products too rich in carbonic acid are grey. Another cause affecting the whiteness of the product is the formation of anhydrous oxide of lead, which is red or yellow. A sample of this red product gave on analysis:—

Oxide of lead	93.70
Carbonic acid	5.31
Water	0.90

99.91

Or 32.22 per cent carbonate of lead, 12.05 of hydrate, and 55.64 of anhydrous oxide. This anhydrous oxide is produced when the supply of acetic acid and water in the chambers is deficient.

Utilisation of Residues of Manganese in the Glass Manufacture.—The solutions of manganese, resulting from the manufacture of chlorine, may advantageously replace peroxide of manganese in glass works. The acid liquid is poured into a large wooden vat, which it fills to the height of one-third, and ground carbonate of lime is added. When the effervescence is over, the rose-coloured solution is decanted, free from iron, which has been precipitated by the chalk. The solution is now placed in a second vat with slaked lime, so as to produce a thick mixture. This turns brown rapidly on the surface. It is dried, and calcined in contact with air, till the brown colour is completely developed. The residue is then ground, and washed with water to remove the chloride of calcium.

MISCELLANEOUS.

A Christmas Puzzle for Chemists.—Mention an inorganic compound having for its distinctive name a word of nine letters, five of which are the vowels a, e, i, o, u, disposed in their alphabetical order.

University of London.—The following are lists of the candidates who have passed the recent Examinations:—*M.S. Examination* (Pass List).—Rickman John Godlee, B.A. (Gold Medal), University College. *B.S. Examination* (Pass List).—First Division. T. Barlow, B.Sc., University College; H. Colgate, University College; R. C. Lucas, Guy's Hospital; C. A. Rayne, University College; E. M. Skerritt, B.A., University College. *Examinations for Honours*—(B.A. and B.Sc. conjointly). *Logic and Moral Philosophy*.—First Class. F. Gotch, B.A. (Scholarship), University College; B. J. Leverson,

B.A., University College. Second Class. H. S. P. G. Chuckerbutty, B.A., University College; R. Lovett, B.A., Cheshunt College, and J. C. Witton, B.Sc., Royal School of Mines (equal); E. R. Hollings, B.A., private study, and L. M. Simmons, B.A., City of London School and private tuition (equal). Third Class. A. G. Savile, B.A., private study, and J. W. Thompson, B.A., University College (equal); W. A. Foxwell, B.A., Wesleyan College, Taunton, and H. Norburn, B.A., private study (equal). (B.Sc. only). *Chemistry*.—First Class. A. S. Napier, Owens College, and J. C. Witton, Royal School of Mines (equal). Third Class. J. A. Hullard, University College, and L. Lyell, private study (equal). *Geology and Palaeontology*.—Second Class. H. S. Robertson, Old Trafford School and Owens; S. H. Vines, Christ's, Cambridge, and Guy's Hospital; L. Lyell, private study; A. W. Fuller, Owens and Emmanuel, Cambridge. Third Class. W. B. Worthington, Owens College; A. S. Napier, Owens College. *Zoology*.—First Class. A. M. Marshall (Scholarship), St. John's College, Cambridge. Second Class. S. H. Vines, Christ's, Cambridge, and Guy's Hospital; L. Lyell, private study.

Fletcher's New Low-Temperature Burner and Foot-Blower.—We have previously had occasion to notice some of Mr. Fletcher's improved appliances for the production and application of heat from gas. The "new low-temperature burner" by the same inventor seems likely to be not less widely appreciated. It gives a range of temperature varying, at the will of the operator, from a mere current of warm air to bright redness, and so perfectly under control that it may be advantageously used for drying, for prolonged digestion and evaporation, and a variety of other operations. It is considered likely to supersede to a great extent hot-air baths, water-ovens, sand-, oil-, water-, steam-, and solution-baths—apparatus which are all, from well-known reasons, more or less objectionable. We learn, in proof of the regular and equable character of the heat, that a common glass bottle may be placed on the tripod above the wire gauze at the top of the apparatus, and heated to any temperature that may be desired without the risk of breakage. When very low temperatures are required, below, or not much exceeding, the boiling-point of water, the gas is lighted through the aperture in the side of the furnace, and burns below the wire gauze. If a red heat is wanted, the light is applied above the wire, where the gas burns with a clear blue flame. By means of a specially adapted "blast-tube," the temperature can be raised to a bright yellow heat, bordering upon full whiteness, being regulated by the respective quantities of air and gas supplied. The "foot-blower" is an improved bellows which may be used with any kind of table blowpipe or laboratory blast-furnace; it appears convenient for working, well arranged, and not likely to get out of order.

NOTES AND QUERIES.

Petroleum.—A cellar has had petroleum stored in it. Is there any effectual method of getting rid of the smell? If you can help me to a solution of this difficulty you will oblige.—FRANK P. PERKINS.

Discharge for Chlorine.—Can any of your numerous readers inform me which is the least expensive discharge for chlorine from textile fabrics without affecting the colour?—A CONSTANT READER.

Sulphide of Sodium in Black-Ash.—(Reply to "A Subscriber.")—200 grs. in fine powder, 4 litre H₂O; temp. 44° C. Allow to stand for, say, two hours, with frequent stirring; filter. 250 c.c. (= 100 grs. dry black-ash) for sulphides, decant into basin, add standard solution (PbNO₃) till all the sulphides are precipitated; nitrate of lead paper as test.—W. SIMMONDS.

Fuller's Earth and Resin Oil.—Crude resin oil being generally turbid, Fuller's earth, as well as other varieties of clay, is sometimes used as a clarifier. The powdered clay is mixed with the oil, stirred, and, when it has subsided to the bottom of the tank, the oil is filtered and comes out quite clear. But this is not literally refined oil. Crude resin oil contains a certain proportion of undecomposed resin, pyrogenous acid, liquid hydrocarbons of widely different boiling-points, also solid homologues of naphthalin. To refine this crude oil it is necessary to re-distil it with slaked lime, and separate the successive products of the distillation. Having had considerable practical experience in the matter, I could give A. K. C. any further information he might require.—P. C.

 Size or varnish from gum-lac, 72
 Slags, use of, 241
 Smith, A. P., analysis of cigar-ash (Havannah), 261, 324
 H. A., chemistry of sulphuric acid manufacture, 123
 L., corindon of N. Carolina, Georgia, and Montana, 124
 corundum of N. Carolina, Georgia, and Montana, 107
 Soap-lyes, action on incandescent metals, 170
 Soaps and perfumery with an aluminous base, 23
 Society for the Promotion of Scientific Industry, 191
 Soda caustic, 170
 formiate, action on benzoic acid, 97
 action on sulpho-benzoic and benzoic acids, 279
 hydrosulphite, to determine aniline colours quantitatively, 109
 hydrosulphite, to determine ferric oxide, 44
 manufacture, 280
 tungstate of, detection of blood-spots by means of, 325
 Sodium, acetamide and ethylate of, 7
 amalgam, products of the reduction of acetophenon with, 196
 sulphide in black ash, 326
 Soils, nitrification in, 81
 Solar atmosphere, spectrum, 170
 diameter, 238
 extent of variation, 293
 heat, reflection at the surface of Lake Leman, 43
 physics, 125
 protuberances, 32, 305
 scoriae, Zollner's theory, 169
 spots, 32, 82, 279
 system, constitution and origin of, 305
 Sonnenschein, M., detection of blood-spots by means of tungstate of soda, 325
 Sonstadt, E., antiseptic and disinfecting power of iodate of calcium, 297
 compound of starch with iodine, 248
 phosphorus a test for iodates, 288
 Sorbic acid, 215
 South London School of Chemistry, 134
 Soxhlet, H., casein and coagulation, 325
 Specific gravity bottle for liquids spontaneously inflammable in contact with air, 211
 of rubies and sapphires, 101
 Spectra of iron and other metals, 82
 of the uranium salts, 47, 113, 164, 233, 244, 257, 268
 Spectrum, determining the wavelengths in, 107
 of chlorophyll, 105
 of the Comet III. of 1873, 169
 of the solar atmosphere, 169

- Spontaneous combustion of hay, 10
generation, 194
Stamm, A., quantitative determination of aniline colours by means of hydrosulphate of soda, 109
Standard trial plates, preparation of to be used in verifying the composition of the coinage, 323
Starch, compound of with iodine, 248
Steam for extinguishing fires, 72
Steel, modifications of the magnetic power of, by tempering and annealing, 70
new method of tempering, 262
Stereoscopic proofs on glass, 250
Story-Maskelyne, N., mineralogical notices, 299
Strakosch, J., nitro- and amidobenzyllamid, 204
Stroboscopic determination of the pitch of tones, 157
Strontium and calcium, dioxides of, 322
Strover, Capt. G. A., metals and minerals of Upper Burmah, 187
Struvite, new deposit, 83
Strychnia bromide, preparation, 264
Succinic acid, action of bromine on the water-salts of, 246, 260
transformation into maleic acid, 58
malic, and tartaric acids, the chemical constitution of, 75, 87, 101
Sugar, artificial, 110
beet-root, removal of potassic salts from solutions obtained in the manufacture of, 72
beet-root, respiration and the inclosed air of, 20
determining by means of a salt of iron, 240
grape and milk, examination of, 170
in vine leaves, 293
Sugars, determination, 44
Sulfon acids, nitric compounds into, 10
Sulph-hydantoin, 83
of sodium in black ash, 326
Sulphide, hydric, manipulation of, 64
Sulpho-acids, preparation, 205
Sulpho-carbonic acid, new derivatives of, 21
Sulpho-carbonic ether, 21
Sulpho-carbonyl-chloride, action on amides, 294
Sulpho-ortho-toluidic acid, 196
Sulpho-salts, new, 264
Sulphur and tellurium, detection on ores, 227
determining, 226
estimation in iron and steel, 229
in pig-irons, &c., 248, 266, 276
existence and dissociation of the tetrachloride of, 196
Sulphuric acid, action upon substituted anilines, 20
combinations of chloral with, 204
reduction by hydrogen, 13
Sun, cyclones of, compared with those of our atmosphere, 59
M. Vicaire's physical theory of, 107
on the elements in, 175
presence of magnesium in the border of, 43, 195
spots, and dark nucleus of the sun, 9
Sun's diameter, 240
Supersaturation, phenomena, 57
Sutton, T., ordinary wet colloidal process, 250
- TACCHINI, M., presence of magnesium at edge of the sun, 195
spectral observations which are in discord with some theories of solar spots, 82
- Tacchini's last note, reply to, 202
Tannic acid, nature and constitution of, 180
Tannin, clarification of beer by, 34
Tartaric, succinic, and malic acids, chemical constitution of, 75, 87, 101
Tarry, M., direction and force of the wind, suppression of vanes, application to cyclones, 314
cyclones of the sun compared with those of our atmosphere, 59
Tartar substitute in grain dyeing, 325
Tauro-carbaminic acid, 280
Tea, 186
detection of adulteration of, 210
iron in, 256, 275
filings in, 259, 287, 302
Teas, analyses of, 307
Teachers of chemistry in London, 134
Telegraphic system, optical, 59
Tellurium and sulphur, detection in ores, 227
Tellurousacid, reaction, 227
Temperature, maintaining nearly constant, 239
Temperatures, high, 174
Terebin, 32, 108
hydrochlorate, 141, 264
Terebic and pyroterebic acids, 204
Tetrachloride of sulphur, 196
Tetranickelous phosphide, 323
Thallium, cyanide, 280
Thermic researches on saline solutions, 70
Thermo-dynamics, 70, 82, 108, 125, 141, 169
Thocymol and oxycymol, 20
"Third Annual Report of the Deputy Master of the Mint" (review), 56
Thompson, L., iron filings in tea, 302
Thoracic wall, action of the respiratory apparatus after opening, 238
Thorpe, T. E., "Quantitative Chemical Analysis" (review), 193
Thyreoiditis, acute, called epidemic goitre, 239
Tiemann, M., analysis of water, 98
Tide, propagation at different points on the French coast, 125
Tissandier, M., meteorological observations in a balloon, 263
Titanic acid, determination in titaniferous iron ores, 93
Titanium and vanadium, presence and determination of in the basalts of the neighbourhood of Clermont-Ferrand, 313
Titanium chloride, compound with ether, 8, 109
Toluol, certain haloid derivatives of, 205
Tommasi, M. D., combination of urea with chloracetyl, 27
Toning, suppression of gold in, 110
Toxicological detection of phosphorus in presence of fatty bodies, 325
Transit of Venus, influence of atmospheric refraction at the instant of contact, 306
Trial plates, preparation of, used in verifying the composition of the coinage, 323
Tribe, A., specific gravity bottle for liquids spontaneously inflammable in contact with air, 211
Tribromacetic acid, 239
Trinity College, Dublin, 138
Trinitro-naphthaline, 20
Tromen, M. de, comparing samples of gunpowder, 158
means of comparing powders with one another, 71
Tronquoy, M. de, application of aniline to photography, 60
- Truchot, M., proportion of carbonic acid in the air, 213
Tungstate of soda, detection of blood spots by means of, 325
Turacin, 201
Turbinage of frozen wines, 70
